
In the public debate and media, it has been suggested that there currently is a “loneliness epidemic” in Western societies. To shed light on this pressing issue we investigated whether age-related changes in loneliness found in early studies also pertain to later-born cohorts, and whether mastery and self-efficacy have become increasingly important for explaining differences in loneliness. We used data from the Longitudinal Aging Study Amsterdam (LASA). Observations were of 4,880 Dutch people aged 55 and older between 1992 and 2016. We employed multi-level regression analyses incorporating birth cohort while controlling for age. Older adults were less lonely in later-born cohorts, although the effect size was small (d=.11 at age 65 comparing cohorts 1918-1927 and 1948-1957; and d=.11 at age 75 comparing cohorts 1908-1917 and 1938-1947). Furthermore, we found a sharp age-related increase in loneliness; older people were lonelier than younger people (d=.83 comparing age 75 and 95 in cohort 1908-1917; and d=.21 comparing age 55 and 78 in cohort 1938-1947). Age effects thus clearly outweigh cohort effects in size. Increasing levels of mastery and self-efficacy across birth cohorts explain the observed cohort-related decline in loneliness. Mastery contributes similar to the effect size of partner status in the explanation of differences in loneliness. We conclude that there is no evidence of a “loneliness epidemic” among later-born cohorts of older adults relative to earlier-born cohorts. Also, mastery and self-efficacy are crucial to fully understanding loneliness in today’s society.

Objectives: Despite a large body of sociological and psychological literature suggesting that religious activities may mitigate the effects of stress, few studies have investigated the beneficial effects of religious activities among immigrants. Immigrants in particular may stand to benefit from these activities because they often report a religious affiliation and often occupy disadvantaged positions. This study investigates whether private and public religious activities reduce the negative effects of a lack of physical, social, and socio-economic resources on wellbeing among Turkish and Moroccan young-old immigrants in the Netherlands. Method: Using data from the Longitudinal Study Amsterdam, cluster analysis revealed three patterns of absence of resources: physically disadvantaged, multiple disadvantages, and relatively advantaged. Linear regression analysis assessed associations between patterns of resources, religious activities and wellbeing. Results: Persons who are physically disadvantaged or have multiple disadvantages have a lower level of wellbeing compared to persons who are relatively advantaged. More engagement in private religious activities was associated with higher wellbeing. Among those with multiple disadvantages, however, more engagement in private religious activities was associated with lower wellbeing. Public religious activities were not associated with wellbeing in the disadvantaged group.
Conclusion: Private religious activities are positively related to wellbeing among Turkish and Moroccan immigrants. In situations where resources are lacking, however, the relation between private religious activities and wellbeing is negative. The study's results highlight the importance of context, disadvantage and type of religious activity for wellbeing.

Objectives: Older immigrants are affected by an accumulation of adversities related to migration and aging. This study investigates resilience in older immigrants by examining the resources they use to deal with these adversities in the course of their lives. Methods: Data from 23 life-story interviews with Turkish and Moroccan immigrants aged 60 to 69 living in the Netherlands. Results: The circumstances under which individuals foster resilience coincide with four post-migration life stages: settling into the host society, maintaining settlement, restructuring life post-retirement, and increasing dependency. Resources that promote resilience include education in the country of origin, dealing with language barriers, having two incomes, making life meaningful, strong social and community networks, and the ability to sustain a transnational lifestyle traveling back and forth to the country of origin. More resilient individuals invest in actively improving their life conditions and are good at accepting conditions that cannot be changed. Discussion: The study illustrates a link between conditions across life stages, migration and resilience. Resilient immigrants are better able to accumulate financial and social and other resources across life stages, whereas less resilient immigrants lose access to resources in different life stages.

Societal changes and an increase in personal resources are likely to have an impact on the personal relationships of cohorts coming of age. We expect that, in recent times, 1) relationships more often strike a balance in exchanged instrumental and emotional support, and 2) relationships are discontinued more often when there is no balance in exchanged instrumental and emotional support, particularly among non-kin. We compare three birth cohorts from the Longitudinal Aging Study Amsterdam, aged 55-64 years at baseline (early cohort: born 1928-1937, interviewed in 1992; middle cohort: 1938-1947, interviewed in 2002; late cohort: 1948-1957, interviewed in 2012). The results indicate that, in the middle and late birth cohorts, personal relationships are more often characterized by a balance in social support exchanges compared to the early cohort. No cohort differences in the effect of balance on relationship discontinuation are observed. The results suggest increased opportunities and preferences of young-olds to maintain balance in their personal relationships.

Background and Objectives. The general view is that partner-caregiver burden increases over time but findings are inconsistent. Moreover, the pathways underlying caregiver burden may differ between men and women. This study examines to what degree and why partner-caregiver burden changes over time. It adopts Pearlin’s Caregiver Stress Process Model, as it is expected that higher primary and secondary stressors will increase burden and larger amounts of resources will lower burden. Yet, the impact of stressors and resources may change over time. The wear-and-tear model predicts an increase of burden due to a stronger impact of stressors and lower impact of resources over time. Alternatively, the adaptation model predicts a decrease of burden due to a lower impact of stressors and higher impact of resources over time. Research Design and Methods. We used 2 observations with a 1-year interval of 279 male and 443 female partner-caregivers, derived from the Netherlands Older Persons and Informal Caregivers Survey Minimum
Data Set. We applied multilevel regression analysis, stratified by gender. Results. Adjusted for all predictors, caregiver burden increased over time for both men and women. For female caregivers, the impact of poor spousal health on burden increased and the impact of fulfillment decreased over time. Among male caregivers, the impact of predictors did not change over time. Discussion and Implications. The increase of burden over time supports the wear-and-tear model, in particular for women. This study highlights the need for gender-specific interventions that are focused on enabling older partners to be better prepared for long-term partner-care.

Objectives. Previous studies have shown that unmarried older adults are generally at disadvantage in personal networks and social well-being compared to the married. It can be questioned whether their situation has improved in contemporary society, as amongst others the stigma of divorce and being never-married has declined. We hypothesize differential developments in networks and well-being according to marital status (married, widowed, divorced and never-married) across birth cohorts. Method. Data are from the 1993 and 2013 observations of the Longitudinal Aging Study Amsterdam on Dutch people aged 55-69 (N = 2,894) and 70-84 years (N = 2,317). We employ general linear modelling of network size and diversity, received emotional and instrumental support, emotional and social loneliness, and depressive symptoms. Results. The widowed are better off socially in 2013 than in 1993. Similar to the divorced they have a larger network, and similar to the never-married they receive more emotional support and are less emotional lonely. We find some gender-differences in these developments. Discussion. Societal change has not radically altered networks and well-being of unmarried older people. The widowed seem to benefit most, possibly because they are better able to retain relationships after widowhood.

2019

Objectives: We examine gender differences in the experienced burden of partner caregivers using the stress-appraisal model. Gender differences can be explained by differences in conditions of burden (primary stressors, help from others, hours of caregiving, and secondary stressors) and how strong their effects are. Method: The data are from the Netherlands’ Older Persons and Informal Caregivers Survey—Minimum Data Set (N = 1,611 caregivers). We examine mediation and moderation effects using structural equation modeling. Results: Women experience greater partner caregiver burden than men, which is related to women experiencing more secondary stressors (relational and financial problems, problems combining different tasks). For women and men alike, there is a positive association between burden and more primary stressors (partner’s care need indicated by health impairment), help from other caregivers, and secondary stressors. For male caregivers, caregiving intensity also contributes to a greater burden. Discussion: This study corroborates the structural impact of gender on the conditions of as well as their effects on the partner caregiver burden. Reducing the hours of caregiving for male caregivers in severe care situations and helping female and male caregivers deal emotionally with the caregiving situation can reduce the partner caregiver burden.

Publications by Theo van Tilburg, p. 3
Recent societal changes have increased the salience of non-kin relationships. It can be questioned whether network types that are more strongly non-kin-based give more informal care nowadays. We study how informal care use differs according to network type for three birth cohorts. Data from the Longitudinal Aging Study Amsterdam (LASA) on older adults aged 75–84 years, interviewed in 1992, 2002 and 2012, respectively (total sample size N = 2,151, analytical sample having functional limitations N = 926). We found four network types: restricted, family-focused with a partner, family-focused without a partner and wider community-focused diverse networks. Wider community-focused diverse networks are more common in the late birth cohort, whereas restricted networks and family-focused networks without a partner are less common. Logistic regression analyses reveal that those in a family-focused network with a partner use informal care more often than those in the other three network types, and insignificant interaction terms show that this does not differ by birth cohort. Irrespective of their network type, those in the late birth cohort use informal care less often. However, after controlling for need, predisposing and context factors, this cohort-difference is no longer significant. We conclude that despite large-scale societal changes, wider community-focused diverse networks do not provide more informal care than before and that among the functionally impaired, the odds of receiving informal care does not decline across birth cohorts.

Objectives. Like other western countries, the Netherlands has abolished early retirement schemes and is currently increasing the statutory retirement age. It is likely that also older workers with disabilities will be required to work longer. We examine the change in working life expectancy (WLE) with disability of older workers by comparing data from three periods: 1992–1996, 2002–2006 and 2012–2016. Methods. Data are from the Longitudinal Aging Study Amsterdam (LASA). Respondents aged 55–65 with a paid job at baseline were included (N=1074). Disability was measured using the Global Activity Limitations Indicator (GALI). First, a continuous-time three-state survival model was created. Second, WLE with and without disability were estimated using MSM and ELECT in R. The modifying effects of gender and educational level were examined. Results. Among those initially in paid employment, total WLE increased over 20 years. For example at age 58, total WLE increased from 3.7 to 5.5 years. WLE with disability at age 58 increased from 0.8 to 1.5 years. There was no difference in WLE with disability between male and female workers or low- and highly educated workers. Conclusions. Between the 1990s and the 2010s, subsequent generations of older workers with disabilities have extended their working lives. The findings emphasize the importance of workplace interventions that facilitate older workers with disabilities to maintain well-being and work ability. In addition, the question arises whether current exit routes out of the workforce are still adequate.

Third Age adults leaving the labour market are not only armed with broad experience and multiple competencies but also find themselves free of professional obligations while still physically sound. The general theory of Third Age of Laslett sheds a new light on characteristics of ageing adults and their role in society. They are able to engage in society in ways inaccessible to previous generations of older adults. According to Laslett, combining a myriad personal strengths and being free of professional obligations they are challenged to make Third Age a time of personal development by making choices of engagement and civic contribution. To enlighten these issues, this qualitative study focuses on how and under what conditions 23 Third Agers invest their
strengths in unpaid societal and social participation. Their narratives reveal three types of involvement: holistic, inhibited and social consumerist. The holistic pattern and, to a lesser extent, the inhibition pattern meet the expectations of Laslett about the Third Age. The social consumerist pattern, on the other hand, rather refers to disengagement. These observations imply that to facilitate the societal engagement and social participation of this population, civil society organisations need to rethink their goals, activities and procedures.

Klokgieters, S.S., Van Tilburg, T.G., Deeg, D.J.H., & Huisman, M. (2018). Resilience in the disabling effect of gait speed among older Turkish and Moroccan immigrants and native Dutch. Journal of Aging and Health, 30, 711-737. http://dx.doi.org/10.1177/0898264316689324 Objectives: To investigate the factors that inhibit the disabling effect of impairments among citizens who have migrated from Turkey and Morocco and native Dutch according to a resilience perspective. Method: Using data from the Longitudinal Aging Study Amsterdam with 928 native Dutch, 255 Turks, and 199 Moroccans aged 55 to 65, linear regression analysis assessed whether country of origin, mastery, income, and contact frequency modified the relationship between gait speed and activity limitations. Results: Turks, but not Moroccans, demonstrated stronger associations between gait speed and activity limitations than the Dutch. Mastery modified the association among the Dutch and the Turks. Income modified the association only among the Dutch. Effect modification by contact frequency was not observed. Discussion: Moroccans and Dutch appeared to be more resilient against impairments than Turks. As none of the resilience factors buffered in all three populations, we conclude that resilience mechanisms are not universal across populations.

bescherming in de ouder wordende bevolking (pp. 35-45). Den Haag: Sociaal en Cultureel Planbureau.

The prevalence of loneliness among Turkish- and Moroccan-Dutch older adults is higher than among Dutch older adults of non-migrant origin. Two explanations may account for this difference. (1) The meaning of the concept may differ, or there is differential item functioning. This might result in scores that not only differ in intensity but also in meaning across groups. (2) The position of older migrants is much more vulnerable than of non-migrant older people. Data from the Longitudinal Aging Study Amsterdam were used to examine support for both explanations. Feelings of loneliness are explored among 176 people born in Morocco and 235 people born in Turkey, aged 55–66 years, and living in urban areas. They migrated on average 35 years ago to the Netherlands. They are compared with a matched sample of 292 older people of Dutch origin. The psychometric properties of the loneliness scale are satisfying, although there is some differential item functioning. Older migrants have more frequent social contacts, but are at a disadvantage in other domains. Taking into account differences in social participation, satisfaction with their income, mastery and depressive symptoms, the difference between older migrants’ and non-migrants’ loneliness is reduced to more than half. Being an older migrant and belonging to a minority might further contribute to feelings of loneliness. Interventions should not be directed at stimulating social contact, but rather, for example, at enhancing the appreciation of their social status and at avoiding negative interpretations of the situation.

Loneliness stems from a mismatch between the social relationships one has and those one desires. Loneliness often has severe consequences for individuals and society. Recently an online adaptation of the Friendship Enrichment Program was developed and tested to gain insight in its contribution to the alleviation of loneliness. Three loneliness coping strategies are introduced during the program: network development, adapting relationship standards and reducing the importance of the discrepancy between actual and desired relationships. Data were collected among 239 participants aged 50-86. Loneliness was measured four times using a multi-item scale, and on various days with a single, direct question. Loneliness assessed with the scale declined during and after the program. Scores on loneliness assessed for a specific day however, are more ambiguous. Despite the immediate positive effect of conducting assignments, we did not observe a decline in the single loneliness item score over the course of the program. The online friendship enrichment program seems to reduce loneliness in general, but these effects are not visible on today’s loneliness. Nevertheless, the online intervention to reduce loneliness is a valuable new contribution to the collection of loneliness interventions.

In dit hoofdstuk komen de persoonlijke relaties van ouderen aan de orde. Deze nemen een belangrijke plaats in binnen het leven van ouderen. Regelmachtig contact met kinderen, familie, buren en vrienden bevordert gevoelens van geborgenheid en sociale integratie, en vermindert gevoelens van eenzaamheid. In alle levensfasen is het prettig over een goed functionerend persoonlijk relatienetwerk te beschikken, maar op oudere leeftijd is het belang onmiskenbaar. Veel ouderen worden geconfronteerd met negatieve veranderingen, zoals gezondheidsproblemen, het verlies van dierbaren of institutionalisering. Persoonlijke relaties fungeren als ‘mantel’ en vormen de belangrijkste bron van steun en zorg in moeilijke tijden. Maar persoonlijke relaties veranderen zelf ook, tijdens het ouder worden of als gevolg van een ingrijpende gebeurtenis. In dit hoofdstuk beschrijven we kenmerken van het persoonlijk relationenwerk van ouderen, in hoeverre deze verschillen naar sekse, leeftijd en opleidingsniveau, en hoe relationenwerken veranderen in de levensloop. Daarna bespreken we twee belangrijke uitkomsten van relationenwerken: het verkrijgen van mantelzorg en de ervaren eenzaamheid. Tenslotte vergelijken we ouderen van nu met hun leeftijdgenoten aan het begin van de negentiger jaren. Nieuwe generaties ouderen hebben andere kenmerken dan ouderen voorheen, en verschillen ook in hun sociale relationenwerk. Daarbij hebben we ook kort aandacht voor de virtuele sociale relaties van ouderen.

Objectives: Integration into social networks is an important determinant of health and survival in late adulthood. We first identify different types of non-kin networks among older adults and second, investigate the association of these types with survival rates. Method: Official register information on mortality is combined with data from the Longitudinal Aging Study Amsterdam (LASA). The sample includes 2,440 Dutch respondents aged 54-85 at baseline in 1992 and six follow-ups covering a time span of 20 years. Using latent class analysis, respondents are classified into distinct types of non-kin networks, based on differences in number and variation of non-kin relations, social support received from non-kin, and contact frequency with non-kin. Next, membership in network types is related to mortality in a Cox proportional hazard regression model.
Results: There are four latent types of non-kin networks that vary in network size and support. These types differ in their associations with mortality, independent of sociodemographic and health confounders. Older adults integrated into networks high in both number and variation of supportive non-kin contacts have higher chances of survival than older adults embedded in networks low in either amount or variation of support or both. Discussion: A combination of structural and functional network characteristics should be taken into account when developing intervention programs aiming at increasing social integration outside the family network.

Objectives. To test the interrelation of the naturalistic course of depression in older people with long-term support received. Design Longitudinal cohort study. Methods. A sample of 277 adults age 55–85 years participating in the Longitudinal Aging Study Amsterdam, with clinically relevant depressive symptoms at baseline (scores ≥16 on the Center for Epidemiological Studies Depression Scale) were followed up over a period of 13 years. General estimating equations were used to examine the relation between depression course and emotional/instrumental support received over time. In addition, partner status, gender, and age were tested as modifiers. Results. A 2-way interaction between depression courses types and time showed significant differences in instrumental support received over time in older people with a late-life depression. Three-way interactions showed that associations between depression course and support variables were modified by gender and partner status. Conclusion. Both men and singles, with a chronic course of depression may be at risk to lose emotional and instrumental support over time. Professional attention is needed to prevent a chronic course of late-life depression, and to preserve personal social networks.

This study investigates how resources and constraints (location of family, gender, income, cultural distance to society of settlement, and health) impact the experience of two interrelated dimensions of transnational aging: transnational behavior and transnational belonging. We specify transnational behavior by visitation of the country of origin and transnational belonging by emotional attachment to the country of origin and consideration of return migration. Data come from the Longitudinal Aging Study Amsterdam with interviews held between 2013 and 2014 with 264 Turkish migrants and 205 Moroccan migrants, aged 55–66. Regression analyses reveal that transnational belonging and behavior are explained by different factors. Family-in-laws’ location and gender only play a role in explaining transnational belonging, while cultural distance and self-rated health affect both dimensions, and subjective income only impacts transnational behavior. Results from the stratified analysis show that for Turkish migrants, family location, cultural distance, and health are important in considering return migration, whereas for Moroccan migrants, only cultural distance plays a role. We conclude that the distinction between transnational belonging and behavior is useful in understanding transnational aging and that our resources and constraints approach extends our view on older migrants.

This research investigates how a sense of belonging functions as protective mechanism against loneliness. Inspired by the work of Berry (1980) on acculturation strategies (i.e. integration, assimilation, separation and marginalization), we distinguish migrants who feel a relatively strong
or weak sense of belonging to larger society and those who feel a strong or weak belonging to the “own group.” We expect that more national belonging contributes to less loneliness. We add a transnational perspective by arguing that feelings of belonging to the own group can take place in the country of settlement, but can also be transnational, i.e. a feeling of belonging to the country of origin. Transnational belonging can protect against loneliness, as it acknowledges the importance of place attachment. Using data from the Longitudinal Aging Study Amsterdam on older migrants aged 55–66, we employ latent class analysis and find five national belonging clusters, interpretable in terms of Berry’s acculturation strategies. Further analyses reveal mixed evidence: some aspects of transnational belonging vary with belonging to the own group, but other aspects point to a third dimension of belonging. Regression analysis shows that those marginalized are loneliest and that a transnational sense of belonging contributes to less loneliness. We conclude that Berry’s (1980) typology is useful for interpreting older migrants’ national belonging and that a transnational sense of belonging is apparent among older migrants, but needs to be explored further.

The predictive value of the Theory of Planned Behavior (TPB) on intention and physical activity (PA) over time was examined. Data from the Aging Well and Healthily intervention program (targeting perceived behavioral control and attitude, not subjective norm) were analyzed, including pretest (T0), posttest (T1, except subjective norm) and 4–6 months follow-up (T2, PA outcomes only) (N = 387, M age 72 years). Structural equation modeling was used to test a TPB model. PA was measured subjectively using the Voorrips sports subscale (T0 and T2), items measured perceived increase in PA (T1), and adherence to exercises (T1 and T2). Model fit was good. The TPB explained variation in intention well (R2 .54–.60) and some PA behavior (R2 .13–.16). The intervention successfully got participants to exercise independent of the measured TPB concepts. More TPB studies in the context of interventions are needed.

Objectives. We validate a translated version of the De Jong Gierveld loneliness scale among older migrants from Turkish and Moroccan descent and validate the original Dutch version of the same scale for Surinamese migrants in the Netherlands. Method. The data were derived from a population-based cross-sectional study among community-dwelling individuals aged 55 and older. In addition to translating the DJGLS for these ethnic groups, several statistical analyses were performed to assess the scale’s reliability and validity. Results. The DJGLS proved to be internally consistent and to have adequate convergent validity among all ethnic groups. Latent structure analysis confirmed the two latent factors (emotional and social subscales) in all groups, but also showed that fit was not optimal in most groups. Known groups validity was observed using functional limitations and subjective health as grouping variables. Conclusions. The results provide sufficient support for use of the translated version of the 11-item DJGLS among Turkish and Moroccan older migrants and use of the Dutch version for Surinamese older migrants as a reliable and valid measure of loneliness. Fit of latent structural models varied between good and poor. Further research is needed to investigate ethnic differences in levels and determinants of loneliness.

Publications by Theo van Tilburg, p. 9
Social isolation, the objective characteristics of a situation of a small-sized social network, is frequently mentioned as a major risk factor for loneliness and mental health problems. In contrast to social isolation, loneliness is the subjective experience of a situation as one of an undesired lack of (quality of) certain relationships. Although social isolation is strongly associated with loneliness, there is not a direct simple association between both phenomena. The standards or wishes for specific types of relationships and the varying cognitive discrepancy experienced are crucial intermediates between social isolation and loneliness.

Background. Loneliness is highly prevalent among older people, has serious health consequences and is an important predictor of mortality. Loneliness and depression may unfavourably interact with each other over time but data on this topic are scarce. Aims. To determine whether loneliness is associated with excess mortality after 19 years of follow-up and whether the joint effect with depression confers further excess mortality. Method. Different aspects of loneliness were measured with the De Jong Gierveld scale and depression with the Centre for Epidemiologic Studies Depression Scale in a cohort of 2878 people aged 55–85 with 19 years of follow-up. Excess mortality hypotheses were tested with Kaplan–Meier and Cox proportional hazard analyses controlling for potential confounders. Results. At follow-up loneliness and depression were associated with excess mortality in older men and women in bivariate analysis but not in multivariate analysis. In multivariate analysis, severe depression was associated with excess mortality in men who were lonely but not in women. Conclusions. Loneliness and depression are important predictors of early death in older adults. Severe depression has a strong association with excess mortality in older men who were lonely, indicating a lethal combination in this group.

The Longitudinal Aging Study Amsterdam (LASA) is an ongoing longitudinal study of older adults in the Netherlands, which started in 1992. LASA is focused on the determinants, trajectories and consequences of physical, cognitive, emotional and social functioning. The study is based on a nationally representative sample of older adults aged 55-áyears and over. The findings of the LASA study have been reported in over 450 publications so far (see www.lasa-vu.nl ). In this article we describe the background and the design of the LASA study, and provide an update of the methods. In addition, we provide a summary of the major findings from the period 2011-2015.

In ageing societies, policy makers aim for more contact between informal and formal care-givers as it may enhance the quality of care. So far, the linkage between formal and informal care-givers is generally studied from a one-sided or a single dyadic perspective, without taking into account that care networks of community-dwelling older adults often exist of multiple informal and formal care-givers. The current study examines discussion of care between all potential informal-formal care-
giver dyads in a care network, and relates this to characteristics of the older care recipient, the care network and the care-givers. Seventy-four Dutch older care recipients provided information on all care-givers who helped with five different types of tasks; 410 care-givers reported on the contact between all care-givers identified. Multi-level logistic regression was conducted in 2,150 informal-formal care-giver dyads and revealed that in 26 per cent of all these dyads discussion on care occurred. This was more likely when both care-givers performed multiple types of tasks, the informal care-giver was residing with the care recipient, and contact within the formal and the informal sub-network was higher. To enhance discussion of care between informal and formal care-givers in care networks where no discussion occurs at all, home-care organisations may need to allocate formal care-givers who form a bridge with an extra-residential care-giver of care recipients living alone.

http://dx.doi.org/10.1016/j.socscimed.2014.05.007

Stronger engagement of older adults in social activities and greater embeddedness in networks is often argued to buffer cognitive decline and lower risks of dementia. One of the explanations is that interaction with other people trains the brain, thereby enhancing cognitive functioning. However, research on the relationship between personal networks and cognitive functioning is not yet conclusive. While previous studies have focused on the size of personal networks as a proxy of cognitive stimulation, little attention has been paid to the complexity of the personal network. Adults embedded in a broad range of network relationships (i.e., various relationship types) are likely to be exposed to a wider range of stimuli than adults embedded in a homogeneous network including similar relationship types. We expect that higher numbers of personal relationship types rather than a higher number of similar contacts relate to higher levels of cognitive functioning and slower cognitive decline. Data are from the Longitudinal Aging Study Amsterdam (LASA) and include 2959 Dutch participants aged 54 to 85 at baseline in 1992 and six follow-ups covering a time span of twenty years. Cognitive functioning is assessed with the Mini-Mental State Examination (MMSE), and for network complexity we use the Social Network Index. We test our expectations using fixed-effects regression models. The results reveal that a reduction in network complexity is associated with a reduction in cognitive functioning, which is neither explained by size of the network nor by presence of specific relationship types. However, enhanced complexity has only a marginal buffering effect on decline in cognitive functioning. We conclude that network characteristics and cognitive functioning are intertwined and that their association is mostly cross-sectional in nature.

Supporting Information: http://dx.doi.org/doi:10.1371/journal.pone.0116731.s001

Background: Research on aging has consistently demonstrated an increased chance of survival for older adults who are integrated into rich networks of social relationships. Theoretical explanations state that personal networks offer indirect psychosocial and direct physiological pathways. We investigate whether effects on and pathways to mortality risk differ between functional and structural characteristics of the personal network. The objective is to inquire which personal network characteristics are the best predictors of mortality risk after adjustment for mental, cognitive and physical health. Methods and findings: Empirical tests were carried out by combining official register information on mortality with data from the Longitudinal Aging Study Amsterdam (LASA). The sample included 2,911 Dutch respondents aged 54 to 85 at baseline in 1992 and six follow-ups covering a time span of over twenty years. Four functional characteristics (emotional and social loneliness, emotional and instrumental support) and four structural characteristics (living arrangement, contact frequency, number of contacts, and number of social roles) of the personal networks were estimated.
network as well as mental, cognitive and physical health were assessed at all LASA follow-ups. Statistical analyses comprised of Cox proportional hazard regression models. Findings suggest differential effects of personal network characteristics on survival, with only small gender differences. Mortality risk was initially reduced by functional characteristics, but disappeared after full adjustment for the various health variables. Mortality risk was lowest for older adults embedded in large (HR=0.986, 95% CI 0.979—0.994) and diverse networks (HR=0.948, 95% CI 0.917—0.981), and this effect continued to show in the fully adjusted models. Conclusions: Functional characteristics (i.e. emotional and social loneliness) are indirectly associated with a reduction in mortality risk, while structural characteristics (i.e. number of contacts and number of social roles) have direct protective effects. More research is needed to understand the causal mechanisms underlying these relations.

A brief review of major conceptual notions and empirical findings within the literature on grandparent–grandchild relationships is presented. Four major topics for understanding the intergenerational relationship are addressed: the historical context, the importance of the relationship, changes over individual time, and culture and variation. The focus is on grandparents and grandchildren from Western societies and who are biologically connected.

This study considers changes in childcare by grandparents between 1992 and 2006 in relation to changes in mothers' need for and grandparents' opportunity to provide childcare. Data from the Longitudinal Aging Study Amsterdam are used to compare two cohorts of Dutch grandparents aged 58 to 68 (N1992 = 181; N2006 = 350). Multilevel regression analysis shows that the probability that grandparents care for their adult daughters' (N1992 = 261; N2006 = 484) increased from .23 to .41. The increase can be ascribed to higher maternal employment rates, growth in single motherhood, reduced travel time, and a decline in the number of adult children. The increase would have been higher if the employment rate of grandparents had not risen.

Deze rapportage laat dertien buitenlandse 'interventies' zien waarvan wetenschappelijk bewezen is dat zij succesvol zijn bij het voorkomen en bestrijden van eenzaamheid door of vanuit de geestelijke gezondheidszorg, gehandicaptenzorg en ouderenzorg. Er zijn projecten waar cliënten in aanraking komen met honden, robot(zee)honden en kippen. Bij elk van deze voorbeelden blijkt eenzaamheid bij deelnemers te verminderen. Andere initiatieven richten zich op een betere omgang door cliënten met zorgverleners of het verbeteren van slecht aangeleerde cognitieve processen. Ook een geheugentraining kan eenzaamheid helpen voorkomen, net zoals een lotgenotengroep voor chronisch zieke ouderen en een computer en internetcursus deze helpen verminderen. Gespreksgroepen, een GGZ-programma dat zich richt op mensen met een psychische stoornis, en activeringsprogramma's om passiviteit te doorbreken zijn andere succesvolle voorbeelden. Ook het inzetten van vrijwilligers als integraal onderdeel van zorgteams blijkt een positief effect te hebben op het verminderen van isolement en mogelijkheden om vriendschappen te ontwikkelen. Om toepassing in Nederland te vereenvoudigen, zijn de...
interventies onderverdeeld in een aantal categorieën, namelijk naar werkwijze (één-op-één vs. groepsinterventies), aard (vertrouwd en veilig voelen; bezig zijn, afleiding, contacten; persoonlijke vaardigheden en vaardigheden gericht op meer kunnen) en setting van de interventie (intramuraal vs. extramuraal). Bij het trekken van conclusies zijn verschillende wetenschappelijke kanttekeningen te maken. Zo kan de selectie van deelnemers effect hebben op het resultaat, is er niet altijd een controlegroep gebruikt, zijn alleen studies met een positief resultaat opgenomen en is het aantal deelnemers over het algemeen klein. Daarom laat dit rapport vooral zien dat er verschillende buitenlandse interventies zijn die als inspiratie gebruikt kunnen worden voor toepassing in de Nederlandse langdurige zorg. Voor toepassing in de Nederlandse context is nodig dat aansluitend bij één van de genoemde interventies in een vooronderzoek gekeken wordt op welke wijze het achterliggende idee van de interventie in te zetten is in de langdurige zorg in Nederland.

We examine the extent to which coping options endorsed by older adults help alleviate loneliness, and experiences with loneliness influence the coping options. Two ways of coping are distinguished: problem-focused, i.e., improving one’s relationships, and emotion-focused, i.e., lowering one’s expectations about relationships. Loneliness is assessed using three observations over 6 years among 1,033 61- to 99-year-old respondents in the Longitudinal Aging Study Amsterdam. Combining the first two observations yielded four loneliness types: not lonely at T0 and T1, recently lonely, persistently lonely, and recovered from loneliness. Between the second and third observations, respondents were asked to evaluate which coping options lonely peers described in various vignettes had. From this, individual coping scores were calculated. The option to improve relationships did not affect the likelihood of one’s own loneliness, and the option to lower expectations even increased it. Compared to non-lonely respondents, recently lonely ones endorsed both ways of coping equally frequently, persistently lonely ones endorsed improving relationships less frequently and lowering expectations more frequently and recovered respondents endorsed improving relationships equally frequently and lowering expectations more frequently. We conclude that considering various ways of coping does not help alleviate loneliness and that persistently lonely and recovered respondents are at risk of a circular process with loneliness experiences resulting in considering lowering expectations more frequently, which results in a greater likelihood of loneliness, thus contributing to sustaining or re-establishing loneliness.

Supplement: http://esr.oxfordjournals.org/content/31/3/243/suppl/DC1

Divorce increases the risk of loneliness. With divorce increasingly becoming a normal life event, societal changes are now challenging this idea as regards to current cohorts. We hypothesize that the relative strong feelings of loneliness among divorcees, compared with married people, has diminished over time. Using 1992, 2002, and 2012 data sets of 54–65-year-old people, we
examine the impact of divorce on loneliness over 20 years. We compare those who are divorced or remarried to people married for the first time, and differentiate the supportiveness of the partnership. The results show that for both emotional and social loneliness, divorcees were lonelier than respondents in their first marriage; remarried divorces were socially lonelier than respondents in their first marriage. Respondents with a supportive partnership were less emotionally and socially lonely than respondents without a partnership or with a less supportive partnership. The main finding is that, compared with 1992, the divorcees are less socially lonely in 2002, with a smaller and non-significant further decrease in loneliness in 2012. This suggests that the social position of divorcees has been improved over the past two decades.

2014

Background. As the prevalence of chronic disease amongst older workers is high and increasing, it is important to know if the large subgroup of older workers with chronic disease has specific needs when it comes to prolonging participation in paid work. Objectives To investigate differences and similarities in predictors of having paid work in workers aged 55+ with and without chronic disease. Methods. Workers aged 55–62 years were selected from the 2002–2003 cohort of the Longitudinal Aging Study Amsterdam (n = 333). Potential predictors were: health, personality, work characteristics, and demographics. Per potential predictor, a logistic regression coefficient for ‘having paid work in 2005–2006’ was calculated for workers with and without chronic disease. A pooled estimate was computed and differences between the pooled estimate and the coefficients were tested. Results. Follow-up data were available for 95 %, of whom 67 % still had paid work. Predictors of having paid work were similar for workers with and without chronic diseases, except for physical workload ($\chi^2 = 5.37; DF = 1$) and psychosocial resources at work ($\chi^2 = 5.94; DF = 1$). Having more psychosocial resources (OR = 3.57; 95 %CI 1.33–10.0) was predictive for having paid work in workers with chronic disease and not in workers without chronic disease. Lower age, more weekly working hours, no functional limitations, fewer depressive symptoms, lower neuroticism scores, and more sense of mastery were significantly associated with having paid work in all workers. Conclusions. Differences between predictors of having paid work between workers with and without chronic disease should be taken into account when aiming to prevent exit from the workforce. In particular the vulnerable subgroup of older workers with chronic disease and low psychosocial resources at work is more likely to quit working.

Background. Known risk factors for Alzheimer's disease and other dementias include medical conditions, genetic vulnerability, depression, demographic factors and mild cognitive impairment. The role of feelings of loneliness and social isolation in dementia is less well understood, and prospective studies including these risk factors are scarce. Methods. We tested the association between social isolation (living alone, unmarried, without social support), feelings of loneliness and incident dementia in a cohort study among 2173 non-demented community-living older persons. Participants were followed for three years when a diagnosis of dementia was assessed (Geriatric Mental State (GMS) Automated Geriatric Examination for Computer Assisted Taxonomy (AGECAT)). Logistic regression analysis was used to examine the association between social isolation and feelings of loneliness and the risk of dementia, controlling for sociodemographic factors, medical conditions, depression, cognitive functioning and functional status. Results. After adjustment for other risk factors, older persons with feelings of loneliness were more likely to develop dementia (OR 1.64, 95% CI 1.05 to 2.56) than people without such feelings. Social
isolation was not associated with a higher dementia risk in multivariate analysis. Conclusions. Feeling lonely rather than being alone is associated with an increased risk of clinical dementia in later life and can be considered a major risk factor that, independently of vascular disease, depression and other confounding factors, deserves clinical attention. Feelings of loneliness may signal a prodromal stage of dementia. A better understanding of the background of feeling lonely may help us to identify vulnerable persons and develop interventions to improve outcome in older persons at risk of dementia.

Objective. This work aims to gain insight into the long-term impact of depression course on social network size and perceived loneliness in older people living in the community. Methods. Within a large representative sample of older people in the community (Longitudinal Aging Study Amsterdam (LASA)), participants with clinically relevant levels of depressive symptoms (scores >16 on the Center for Epidemiological Studies Depression Scale) were followed up over a period of 13 years of the LASA study (five waves). General estimating equations were used to estimate the impact of depression course on network size and loneliness and the interaction with gender and age. Results. An unfavorable course of depression was found to be associated with smaller network sizes and higher levels of loneliness over time, especially in men and older participants. Conclusions. The findings of this study stress the importance of clinical attention to the negative consequences of chronicity in depressed older people. Clinicians should assess possible erosion of the social network over time and be aware of increased feelings of loneliness in this patient group.

Objective: This study investigates whether the rate of decline in older persons’ hearing status is associated with the rate of decrease in their psychosocial health and explores moderation by baseline hearing status, health-related factors, and sociodemographic factors. Method: Multilevel analyses were applied to data of 1,178 older participants from the Longitudinal Aging Study Amsterdam (LASA), covering 3 to 7 years of followup. Results: Faster decrease in speech-in-noise recognition was significantly associated with more increase in loneliness for persons with a moderate baseline speech-in-noise recognition (emotional and social loneliness) and for persons who recently lost their partner (emotional loneliness). No relationship was found with depression. Discussion: The results indicate that faster hearing decline results in more increase in loneliness in specific subgroups of older persons: in persons with an already impaired hearing and in widow(er)s. Monitoring older persons’ hearing seems important and may be a relevant starting point for targeted loneliness prevention efforts.

Schoenmakers, E.C., Fokkema, T., & Van Tilburg, T.G. (2014). Eenzaamheid is moeilijk op te lossen en treft niet alleen ouderen. *Demos, 30* (8), 5-7. [http://hdl.handle.net/1871/51726](http://hdl.handle.net/1871/51726)

Een op de drie Nederlanders voelt zich eenzaam. Eenzaamheid krijgt veel aandacht in de media en bestrijding ervan is een speerpunt in landelijk en lokaal overheidsbeleid. De nadruk ligt vaak te eenzijdig op eenzaamheid onder ouderen. En hoe kan eenzaamheid het beste worden aangepakt? Of moeten we er mee leren leven?

Awareness of risk factors for loneliness is a prerequisite for preventive action. Many risk factors for loneliness have been identified. This paper focuses on two: poor health and widowhood. Preventive action by developing a satisfying social network requires time and effort and thus seems appropriate for people unexposed to risk factors, i.e. third agers and non-lonely persons. The third age is the period in old age after retirement, before people's social relationships deteriorate. This paper addresses three questions: Are older adults aware of poor health and widowhood as risk factors for loneliness? Are there differences in awareness between third and fourth agers? Are there differences in awareness between lonely and non-lonely older adults? After being introduced to four vignette persons, 920 respondents from the Longitudinal Aging Study Amsterdam were asked whether they expected these persons to be lonely. Older adults, especially third agers, expected peers exposed to the risk factors to be lonely more often than peers who were unexposed. The results indicate that awareness of loneliness-provoking factors is high among third agers, which is a first step towards taking actions to avoid loneliness. Compared to lonely older adults, non-lonely ones expected peers to be lonely less often, suggesting the latter's lower awareness of the risk factors. The results provide evidence for policy makers and practitioners that combating loneliness might require early action.

This study examines the degree to which the sharing of parental care, as indicated by the amount of children participating in caregiving and by equality in caregiving intensity, is associated with similarities among sibling characteristics. A selected sample of 186 parents with at least two children was asked to report on the assistance provided by all their children. Results reveal that in most families the care was shared between children. However, there was a large variation in caregiving intensity. Multivariate regression analyses show that similarities in employment status among children predicted a higher chance that the care was shared and a higher degree of equality in caregiving intensity among siblings. Similarities in partner status and emotional support exchanges with parents were associated with the equality among siblings in caregiving intensity. Results from this study suggest that siblings with similar characteristics and opportunities are more likely to share care (equally).

Ouderen zijn eenzaam en alleen, is de gangbare opvatting. Door individualisering en andere ontwikkelingen in de samenleving neemt eenzaamheid toe. Tegelijk hebben we door een betere gezondheid en technische ontwikkelingen als ICT meer mogelijkheden tot op hoge leeftijd contact te onderhouden. Toenemende eenzaamheid, waar of niet waar?

Ouderen zijn eenzaam en alleen, is de gangbare opvatting. Door individualisering en andere ontwikkelingen in de samenleving neemt eenzaamheid toe. Tegelijk zijn er meer mogelijkheden tot op hoge leeftijd contact te onderhouden. Eenzaamheid komt meer voor dan vroeger, waar of niet waar? [Ten dele gebaseerd op de tekst gepubliceerd in Gerõn, 2014]

Objectives. To describe the degree of loneliness among the visually impaired elderly and to make a comparison with a matched reference group of the normally sighted elderly. In addition, we examined self-management abilities (SMAs) as determinants of loneliness among the visually impaired elderly. Methods. In a cross-sectional study, 173 visually impaired elderly persons completed telephone interviews. Loneliness and SMAs were assessed with the Loneliness Scale of De Jong Gierveld and the SMAS-30, respectively. Results. The prevalence of loneliness among the visually impaired elderly was higher compared to the reference group (50% vs 29%; \( p < .001 \)). Multivariate hierarchical regression analysis showed that the SMA self-efficacy, partner status, and self-esteem were determinants of loneliness. Severity and duration of visual impairment had no effect on loneliness. Discussion. The relationship between SMAs (i.e., self-efficacy) and loneliness is promising, since SMAs can be learned through training. Consequently, self-management training may reduce feelings of loneliness. An adapted version of this paper was published in Journal of Aging and Health, doi:10.1177/0898264311399758.

The authors examined eight personal and contextual conditions associated with starting new relationships with neighbors after short- and long-distance moves. A total of 625 Dutch movers and 1,936 non-movers (57–93 years old) were selected from the Longitudinal Aging Study Amsterdam. OLS linear regression analyses showed that short-distance movers mainly started relationships with neighbors when they did volunteer work. Long-distance movers who moved to rural areas and felt safe in their new neighborhood or moved to areas with lower priced homes also started new relationships with neighbors. Contextual conditions appear to play a larger role than personal ones, especially after long-distance moves.

Objectives: The aim of this study is to increase our understanding of declining network size with aging by differentiating between processes of loss and gain and studying the associations with various health problems. Methods: Six observations of the Longitudinal Aging Study Amsterdam (LASA) across a time period of 16 years are used to study detailed network changes in a large sample of Dutch older adults aged 55 to 85 at baseline. Results: Results from multilevel regression analyses show that network size declines with aging, in particular for the oldest old. The decline in...
network size is to a large degree due to a lack of replacement of lost relationships with new relationships. Results show differential effects of health. Discussion: The older old and people in poor health have limited possibilities to compensate for network losses and may have a serious risk of declining network size in later life.

This paper investigates the trend in sport participation among retirees between 1983 and 2007. Sport participation is important for retirees because of its health benefits and the opportunities it offers for social interaction. Factors that influence sport participation such as educational level, physical limitations, and occupational background have changed during the last decades, possibly accounting for changes in sport participation. Data are from the Amenities and Services Utilization Survey (AVO), a nationally representative Dutch survey with seven observations between 1983 and 2007. The trend in sport involvement, sports club membership, and competition was investigated in a sample of 2,497 male and 1,559 female retirees aged 58–67 years. Increases in participation were observed in sport involvement and sports club membership. This trend can partially be explained by increases in educational level, decreases in the number of retirees with physical limitations, and in those retiring from sedentary jobs. Yet, sport participation seems to have increased for all retirees, regardless of their socio-economic background and health status. Alternative explanations for the observed trend are discussed.

Work-related personal ties following retirement. The current study examines consequences of retirement for the continuation of work-related relationships. The hypothesis is that their inclusion in personal networks after retirement has become more likely since these relationships have become less role-based in today's social-cultural context. Data are from the Longitudinal Aging Study Amsterdam. Members of two cohorts born 1928-1937 (N = 109) and 1938-1947 (N = 131) were interviewed in 1992 and 2002, respectively, with a follow-up three and six years later. Among retirees the likelihood of having work-related relationships in their personal network after retirement increased by 19% in ten years. This suggests that retirement has become less disruptive. Retirees seem more inclined to form intrinsically rewarding work-related relationships that continue to be important following retirement.

About the book: 'Kinship and cohort in an aging society' brings together scholars whose common link is their intellectual interaction with the work of Vern Bengtson, an esteemed family sociologist whose accomplishments include foundational theoretical contributions to the study of families and intergenerational relations as well as the development of the widely used Longitudinal Study of Generations data set. The study began in 1971 and is the basis for Bengtson’s highly influential concept and measurement model, the intergenerational solidarity-conflict paradigm. This book

Publications by Theo van Tilburg, p. 18
serves as an excellent compendium of original research that examines how Bengtson’s solidarity model, a theory that informs nearly all intergenerational and gerontology sociology work performed today, continues to be relevant to scholars and practitioners. Written by internationally recognized scholars, the book’s fifteen chapters are mapped to five major thematic areas to which Bengtson’s research contributed: family connections; grandparents in a changing demographic landscape; generations and cohorts (micro-macro dialectics); religion and families in the context of continuity, change, and conflict; and global cross-national and cross-ethnic concerns. Some key strengths of the book are the diversity of foci and data sources and the strong attention given to global and international issues. ‘Kinship and cohort in an aging society’ will appeal to scholars working in sociology, psychology, gerontology, family studies, and social work.

Older people increase their well-being and contribute to the community when they volunteer. Therefore, policy-makers sometimes consider supporting older volunteers. However, they reach different conclusions on whether they should introduce policies for older volunteers, and on what policy would be the most suitable. This article studies how policies for older volunteers emerged in Germany and Italy, both countries having one of the oldest populations in the world. It explores the political discourse on older volunteers, and how this discourse translates into policies. To do this, the article presents data collected in expert interviews and document analysis. Findings show that German policy-makers stress the contribution of volunteering to older people’s well-being and have introduced policies for older volunteers. Italian policy-makers, in contrast, frame older volunteers as social service providers and have decided not to single out specific age groups in their policies for volunteers. Moreover, the policies are influenced by the policy-makers' perceptions and path-dependencies, meaning policies and institutions that were introduced in the past. These findings suggest that whether or not policies for older volunteers emerge depends less on the characteristics of the older population and more on the society and its political traditions.

Objective: Older couples are likely to be confronted with health problems of both spouses and these health problems may negatively influence their marital satisfaction. The present study examined these possible negative effects using a dyadic perspective. Method: Data from 78 independently living older couples were analyzed using the Actor-Partner Interdependence Model (APIM). Health problems were modeled as a latent factor of functional disability, the number of chronic diseases, and self-rated health. The couple’s health context, that is, similarity or dissimilarity, was examined with an actor-partner interaction variable. Results: For wives, spousal health problems were negatively associated with their marital satisfaction, but only under the condition that their own health was relatively good. For husbands, neither own nor spousal health problems were associated with their marital satisfaction. Discussion: Future research focusing on older couples needs to consider the couple’s health context next to health at the individual level.

http://dx.doi.org/10.1017/S1041610212001202
Background: Prevalence of depression is twice as high in women as in men, also in older adults. Lack of social support is a risk factor for late-life depression. The relation between depression and social support may be different for men and women. Methods: Data from the Longitudinal Aging Study Amsterdam were used to investigate gender differences in the relation between social support and depression in a population-based sample aged 55-85 years, with n = 2,823 at baseline and using the 13-year follow-up data on onset of depression. Results: Respondents without a partner in the household, with a small network, and with low emotional support were more often depressed, with men showing higher rates of depression than women. A high need for affiliation was associated with depression in women but not in men. Lack of a partner in the household and having a small network predicted onset of depression in men but not in women. In respondents with high affiliation need and low social support, depression rates were higher, with men being more often depressed than women. Conclusions: Low social support and a high need for affiliation were related to depression in later life, with men being more vulnerable for depression than women. Considering the serious consequences of depression, especially in older people, it is important to identify the persons with low social support and a high need for affiliation, and to help them to increase their social support or to adjust their needs.

http://hdl.handle.net/1871/41435

Objectives. Research on age-related changes in personal networks has found compelling evidence for socioemotional selectivity theory and exchange theory holding that older adults experience a decline in less emotionally close nonkin relations as they age. However, recent societal developments are likely to have increased the salience of nonkin relations. We hypothesize that age-related decline in the proportion of nonkin in personal networks has been delayed or is slower in late birth cohorts of older adults compared with earlier cohorts. Method. Seven observations by the Longitudinal Aging Study Amsterdam covering a time span of 17 years since 1992 were analyzed using multilevel regression analysis. The sample had 12,949 person-year observations from 3,516 respondents born between 1908 and 1937. Results. Age-related decline in the proportion of nonkin is absent for cohorts born after 1922 and large for cohorts born in 1922 and before. Mediating variables for health and other resources did not explain cohort differences in age-related change. Discussion. The salience of nonkin relationships is likely to have increased due to societal changes, resulting in absence or delay of decline in later cohorts. The findings raise the need for a reevaluation of old age and the creation of new theoretical perspectives.

http://hdl.handle.net/1871/41407

Guided by trends of increased prevalence and social acceptance of stepfamilies, the authors argue that stepparents are more likely to include stepchildren in their personal network in recent times. Data are from observations by 2 studies: (a) the Living Arrangements and Social Networks of Older Adults Study and (b) the Longitudinal Aging Study Amsterdam in 1992-2009 of 247 Dutch stepparents age 54-91 years. The results revealed that in 1992, 63% of the stepparents had stepchildren in their personal network, and this percentage increased to 85% in 2009. The network membership of stepchildren was less likely for stepparents from living-apart-together partnerships. Stepmothers less often included stepchildren in their personal network than stepfathers. Both effects may be understood in terms of family commitment. Stepfamily boundaries have become more permeable over time, suggesting that there is an increased potential for support exchange and caregiving within stepfamilies.

Given population aging and the productive potential of older people, it is important to examine how individual and societal developments affect social engagement in later life. The study aimed to disentangle the effects of age, aging, and cohort on volunteering among the young old. Using data from the Longitudinal Aging Study Amsterdam, we examined volunteering rates of young olds (N=2,745) in two decades: those being 55-69 years old in 1992 and their age-peers in 2002. Six-year follow-up on both cohorts allowed for cohort-sequential analyses. Multilevel logistic regression
analyses revealed that (i) regardless of age, the 2002 cohort volunteered more often than the 1992 cohort, (ii) in 6 years’ time volunteering increased for the 55- to 59-year-olds, stabilized among the 60- to 64-year-olds, and declined among the 65- to 69-year-olds, and (iii) these age-differential changes were observed in both cohorts. These effects remained significant after adjusting for gender, education, religious involvement, health, employment status, network size, and partner status. A higher education, religious involvement, staying in good health, and maintaining a large network increased the likelihood of volunteering. Unobserved factors, such as a more positive view on aging within society, may also account for the large increase in volunteering among the recent cohort of young olds.

This study examined whether past grandparental child care is related to present support from adult children. On the basis of social exchange theory, the authors expected that grandparental child care creates a debt that is repaid in the form of receiving support later in life. Using data from the Longitudinal Aging Study Amsterdam (N = 349 parents, N = 812 adult children), the authors found that grandparents who frequently provided child care for sons in the past more often received instrumental and emotional support from these sons approximately 13 years later than grandparents who less frequently provided child care. Investments in daughters did not pay off. Instrumental support other than child-care provision did not predict receiving support from either sons or daughters, but emotional support did. These results support the notion of long-term reciprocity in parent–child relationships, but its importance depends on the child's gender and the type of earlier investment.

http://dx.doi.org/10.1111/j.1475-6811.2011.01354.x;  
http://hdl.handle.net/1871/41236  
ISSN 1350-4126

This study examined whether grandparents perceive adult grandchildren as frequent and important contacts by analyzing network membership. It additionally examined whether this network membership is related to relationship intensity during childhood. Network membership was assessed in 1992 (397 grandparents, 1,594 adult grandchildren) and at the 2005–2006 follow-up (155 grandparents, 429 adult grandchildren) from the Longitudinal Aging Study Amsterdam. Relationship intensity during childhood was assessed in 1992. One out of four grandparents identified at least one adult grandchild in their personal network. Adult grandchildren who had an intense relationship with their grandparents during childhood were more often in grandparents' network than others. An intense relationship during childhood promotes continuation of the relationship into adulthood and might contribute to grandparent's support potential.

http://hdl.handle.net/1871/39419

Background. Loneliness has a significant influence on both physical and mental health. Few studies have investigated the possible associations of loneliness with mortality risk, impact on men and women and whether this impact concerns the situation of being alone (social isolation), experiencing loneliness (feeling lonely) or both. The current study investigated whether social isolation and feelings of loneliness in older men and women were associated with increased mortality risk, controlling for depression and other potentially confounding factors. Method. In our
prospective cohort study of 4004 older persons aged 65–84 years with a 10-year follow-up of mortality data a Cox proportional hazard regression analysis was used to test whether social isolation factors and feelings of loneliness predicted an increased risk of mortality, controlling for psychiatric disorders and medical conditions, cognitive functioning, functional status and sociodemographic factors. Results. At 10 years follow-up, significantly more men than women with feelings of loneliness at baseline had died. After adjustment for explanatory variables including social isolation, the mortality hazard ratio for feelings of loneliness was 1.30 [95% confidence interval (CI) 1.04–1.63] in men and 1.04 (95% CI 0.90–1.24) in women. No higher risk of mortality was found for social isolation. Conclusions. Feelings of loneliness rather than social isolation factors were found to be a major risk factor for increasing mortality in older men. Developing a better understanding of the nature of this association may help us to improve quality of life and longevity, especially in older men.

Background: Major life events are associated with a change in daily routine and could thus also affect habitual levels of physical activity. Major life events remain largely unexplored as determinants of older adults’ participation in physical activity and sports. This study focused on two major life events, widowhood and retirement, and asked whether these major life events were associated with leisure time moderate to vigorous physical activity (MVPA) and sports participation. Methods: Data from the first (1992-93) and second (1995-96) wave of the Longitudinal Aging Study Amsterdam (LASA), a prospective cohort study with a representative sample of the Dutch population aged 55 and older, were used. Change in marital status and employment status between baseline and follow-up was assessed by self-report. Time spent in MVPA (min/d) and sports participation (yes/no) was calculated based on the LASA Physical Activity Questionnaire. The association of retirement and widowhood with MVPA and sports participation was assessed in separate multivariate linear and logistic regression analyses, respectively. Results: Widowhood - N=136 versus 1324 stable married- was not associated with MVPA (B= 3.5 [95%CI: -57.9;64.9]) or sports participation (OR= 0.8 [95%CI: 0.5;1.3]). Retired participants (N= 65) significantly increased their time spent in MVPA (B= 32.5 [95% CI: 17.8;47.1]) compared to participants who continued to be employed (N= 121), but not their sports participation. Age was a significant effect modifier (B= 7.5 [90% CI: -1.1;13.8]), indicating a greater increase in MVPA in older retirees. Discussion: Our results suggest that the association between major life events and MVPA and sports participation varies by type of major life event and age group. MVPA increased after retirement, but no influence of widowhood was seen.

http://hdl.handle.net/1871/38051

Volunteering in later life attracts attention because its benefits older volunteers, voluntary associations, and society. Unfortunately, researchers and practitioners struggle with the complexity of predicting who volunteers. The authors ask whether a rough identification of older volunteers solely based on age is possible. The authors answer this question by means of structural equation modeling, analyzing international survey data. The findings show that the direct effect of age on the time older people spend volunteering is negligible. Moreover, the age patterns in volunteering created by retirement and declining health are weak. Those findings make age an unsuitable indicator for volunteering in later life. The authors recommend that voluntary organizations and policy makers use personal characteristics, such as health status, when defining their target
groups for programs that encourage volunteering. In addition, researchers should not use an age group when referring to the third age, meaning the active and productive part of old age.

Objectives: A limited amount of information is available on how older adults cope with loneliness. Two ways of coping are distinguished here, i.e., active coping by improving relationships and regulative coping by lowering expectations about relationships. We explore how often older adults suggest these options to their lonely peers in various situations and to what extent individual resources influence their suggestions. Method: After introducing them to four vignettes of lonely individuals, discriminating with regard to age, partner status, and health, 1,187 respondents aged 62-100 from the Longitudinal Aging Study Amsterdam were asked whether this loneliness can be alleviated by using various ways of coping. Results: In general, both ways of coping were often suggested. However, regression analyses revealed that active coping was suggested less often to people who are older, in poor health, or lonely and by older adults who were employed in midlife and have high self-esteem. Regulative coping was suggested more often to people who are older and by older adults with a low educational level and with low mastery. Conclusions: Coping with loneliness by actively removing the stressor is less often seen as an option for and by the people who could benefit most from it. This underlines the difficulty of combating loneliness.

Het sociale leven van oudere volwassenen is gedurende de laatste twee decennia behoorlijk veranderd als gevolg van maatschappelijke ontwikkelingen. Onderliggende processen bij deze veranderingen zijn individualisering en het loslaten van tradities. Er is meer persoonlijke vrijheid in de keuze van leefstijl en identiteit, en grotere persoonlijke verantwoordelijkheid voor het ontwikkelen en in stand houden van een persoonlijk netwerk van sociale relaties. Vriendschappen worden belangrijker.

Suanet, B.A., Broese van Groenou, M.I., & Van Tilburg, T.G. (2012). Informal and formal home care use among older adults in Europe: Can cross-national differences be explained by societal context and composition? *Ageing and Society*, 23, 491-515. [http://dx.doi.org/10.1017/S0144686611000390](http://dx.doi.org/10.1017/S0144686611000390) ISSN 0144-686X [http://hdl.handle.net/1871/33025](http://hdl.handle.net/1871/33025)

Cross-national comparisons used welfare state regimes to explain differences in care use in the...
European older population, yet these classifications do not cover all care-related societal characteristics and limit our understanding of which specific societal characteristics are most important. This study explores to the familialistic culture, welfare state context, and socio-economic and demographic composition add to our understanding of informal and formal care use of older adults in 11 European countries. Using the Survey of Ageing, Health and Retirement (2006), multilevel logistic regression analyses show that, in addition to individual determinants, societal determinants are salient for understanding informal and formal care use. In countries with a less familialistic culture, a high availability of home based services, a larger proportion of women in part-time work and a smaller proportion of 65 years and older in the population, older adults are more likely to receive formal home care, particularly when they have functional limitations. In countries with more residential care, more spending in pensions, more women in part-time employment and a more aged population, older adults with functional limitations are less likely to receive informal care. We can tentatively conclude that the incorporation of societal determinants rather than commonly used welfare state classifications yields more insight in factors that determine older adults informal and formal care use.

Objectives: To describe the degree of loneliness among the visually impaired elderly and to make a comparison with a matched reference group of the normally sighted elderly. In addition, we examined self-management abilities (SMAs) as determinants of loneliness among the visually impaired elderly. Method: In a cross-sectional study, 173 visually impaired elderly persons completed telephone interviews. Loneliness and SMAs were assessed with the Loneliness Scale of De Jong Gierveld and the SMAS-30, respectively. Results: The prevalence of loneliness among the visually impaired elderly was higher compared with the reference group (50% vs. 29%; \( p < .001 \)). Multivariate hierarchical regression analysis showed that the SMA self-efficacy, partner status, and self-esteem were determinants of loneliness. Severity and duration of visual impairment had no effect on loneliness. Discussion: The relationship between SMAs (i.e., self-efficacy) and loneliness is promising, as SMAs can be learned through training. Consequently, self-management training may reduce feelings of loneliness.

Purpose. To assess the degree of participation of the visually impaired elderly and to make a comparison with population-based reference data. Method. This cross-sectional study included visually impaired elderly persons (≥55 years; n=173) who were referred to a low-vision rehabilitation centre. Based on the International Classification of Functioning, Disability and Health (ICF) participation in: 1) domestic life, 2) interpersonal interactions and relationships, 3) major life areas, and 4) community, social and civic life was assessed by means of telephone interviews. In addition, we assessed perceived participation restrictions. Results. Comparison with reference data of the elderly showed that visually impaired elderly persons participated less in heavy household activities, recreational activities and sports activities. No differences were found for the interpersonal interactions and relationships domain. Participants experienced restrictions in household activities (84%), socializing (53%), paid or voluntary work (92%), and leisure activities (88%). Conclusions. Visually impaired elderly persons participate in society, but they participate less than their peers. They experience restrictions as a result of vision loss. These findings are
relevant, since participation is an indicator for successful aging and has a positive influence on health and subjective well-being.

Objective: To determine the possible longitudinal relationships between hearing status and depression, and hearing status and loneliness in the older population. Design: Multiple linear regression analyses were used to assess the associations between baseline hearing and 4-year follow-up of depression, social loneliness, and emotional loneliness. Hearing was measured both by self-report and a speech-in-noise test. Each model was corrected for age, gender, hearing aid use, baseline wellbeing, and relevant confounders. Subgroup effects were tested using interaction terms. Study sample: We used data from two waves of the Longitudinal Aging Study Amsterdam (2001–02 and 2005–06, ages 63–93). Sample sizes were 996 (self-report (SR) analyses) and 830 (speech-in-noise test (SNT) analyses). Results: Both hearing measures showed significant adverse associations with both loneliness measures (p < 0.05). However, stratified analyses showed that these effects were restricted to specific subgroups. For instance, effects were significant only for non-hearing aid users (SR-social loneliness model) and men (SR and SNT-emotional loneliness model). No significant effects appeared for depression. Conclusions: We found significant adverse effects of poor hearing on emotional and social loneliness for specific subgroups of older persons. Future research should confirm the subgroup effects and may contribute to the development of tailored prevention and intervention programs.

Friendship has increased in importance during the last few decades. The study examines whether friendship has become more prevalent in personal networks of older adults. Three cohorts of older persons have been followed since 1992 for 17 years in the Longitudinal Aging Study Amsterdam. The younger cohort had friends more often and retained friends longer than two older cohorts. The differences are related to personal choice, relational competence and greater structural opportunities for making and keeping friends that were available to the younger cohort. Women

Publications by Theo van Tilburg, p. 26
retained same-sex friends longer than men. The oldest women lost cross-sex friends more often than did men. This is related to different gender-specific survival rates and to women’s tendency to retain friendships longer.

Previous research on the care-giver burden experienced by adult children has typically focused on the adult child and parent dyad. This study uses information on multiple informal care-givers and examines how characteristics of the informal care-giving network affect the adult child’s care-giver burden. In 2007, 602 Dutch care-givers who were assisting their older parents reported on parental and personal characteristics, care activities, experienced burden and characteristics of other informal care-givers. A path model was applied to assess the relative impact of the informal care-giving network characteristics on the care-giver burden. An adult child experienced lower care-giver burden when the informal care-giving network size was larger, when more types of tasks were shared across the network, when care was shared for a longer period, and when the adult child had no disagreements with the other members of the network. Considering that the need for care of older parents is growing, being in an informal care-giving network will be of increasing benefit for adult children involved in long-term care. More care-givers will turn into managers of care, as they increasingly have to organise the sharing of care among informal helpers and cope with disagreements among the members of the network.

2010

This study examines the consequences of retirement for the continuation of work-related personal ties. The hypothesis is that their inclusion in personal networks after retirement has become more...
likely because these relationships have become less role based in today’s social-cultural context. Data are from the Longitudinal Aging Study Amsterdam. Members of two cohorts born during the periods 1928-1937 (N = 109) and 1938-1947 (N = 131) were interviewed in 1992 and 2002, respectively, with a follow-up 3 years later. Among retirees, the likelihood of having work-related relationships in their personal network after retirement increased by 19% in 10 years. This suggests that retirement has become less disruptive. Retirees seem more inclined to form intrinsically rewarding work-related relationships that continue to be important following retirement.

Loneliness concerns the subjective evaluation of the situation individuals are involved in, characterized either by a number of relationships with friends and colleagues which is smaller than is considered desirable (social loneliness), as well as situations where the intimacy in confidant relationships one wishes for has not been realized (emotional loneliness). To identify people who are lonely direct questions are not sufficient; loneliness scales are preferred. In this article, the quality of the three-item scale for emotional loneliness and the three-item scale for social loneliness has been investigated for use in the following countries participating in the United Nations Generations and Gender Surveys: France, Germany, the Netherlands, Russia, Bulgaria, Georgia, and Japan. Sample sizes for the 7 countries varied between 8,158 and 12,828. Translations of the De Jong Gierveld loneliness scale have been tested using reliability and validity tests including a confirmatory factor analysis to test the two-dimensional structure of loneliness. Test outcomes indicated for each of the countries under investigation reliable and valid scales for emotional and social loneliness, respectively.

Low birth rates in developed societies reflect women’s difficulties in combining work and motherhood. While demographic research has focused on the role of formal childcare in easing this dilemma, evolutionary theory points to the importance of kin. The cooperative breeding hypothesis states that the wider kin group has facilitated women’s reproduction during our evolutionary history. This mechanism has been demonstrated in pre-industrial societies, but there is no direct evidence of beneficial effects of kin’s support on parents’ reproduction in modern societies. Using three-generation longitudinal data anchored in a sample of grandparents aged 55 and over in 1992 in the Netherlands, we show that childcare support from grandparents increases the probability that parents have additional children in the next 8 to 10 years. Grandparental childcare provided to a nephew or niece of childless children did not significantly increase the probability that those children started a family. These results suggest that childcare support by grandparents can enhance their children’s reproductive success in modern societies and is an important factor in people’s fertility decisions, along with the availability of formal childcare.

Evolutionary explanations of low fertility in modern affluent societies commonly state that low
fertility is the outcome of high parental investments in the quality of their children. Although the empirical evidence that modern parents do face a quantity–quality trade-off is strong, two issues that are relevant from an evolutionary perspective have not received much attention. First, sex differences in the proximate aspects of quality have been largely ignored. Second, the relationship between the quantity of children and their reproductive success in contemporary low-fertility societies remains unclear. In this article, we study the quantity–quality trade-off as a trade-off between the number of children and the mate value and reproductive success of those children. We examine the trade-off in two steps. First, a lower number of children is expected to increase the mate value of these children. Second, greater mate value is expected to lead to greater reproductive success. Using sex-specific indicators of mate value, we test these hypotheses in a representative sample of the Dutch population aged 55–85 in 1992 ($n = 3229$). This sample contains information on three successive generations in which the middle generation has completed fertility. We find support for the first hypothesis, but only partial support for the second hypothesis. A higher number of children is traded off against the mate value of the children, but not against their reproductive success. We conclude that the conditions under which the quantity of children is traded off against their reproductive success depend on the social environment.

Over the past years, older persons' workforce participation has increased and, after years of studying early retirement, the focus has gradually shifted to workforce participation between age 60 and 70 years. Those are the years directly below and above the mandatory retirement age in most of the European countries. We investigate the influence of socio-economic status (SES) on older persons' workforce participation. Moreover, we study whether the importance of private pensions in a country modifies the effect of SES. Survey data from eleven European countries are analysed in multilevel analyses. Results show that paid work in old age is the domain of persons with high SES. Moreover, a high share of private pensions in a country diminishes the influence of occupational prestige on men's workforce participation. This suggests that older persons with low SES deserve particular attention in labour market reforms. Additionally, it suggests that pension reforms be monitored concerning their effects on social inequalities.

This study examines the degree to which siblings’ behaviors and characteristics influence a child’s caregiving. A sample of 186 older parents in need of care with at least two adult children reported on characteristics and caregiving of all their children (N = 703). Multilevel regression models show that there is evidence of children’s joint caregiving efforts: The more care siblings give, the more care the child gives. Results demonstrate that the more sisters a child has, the less care that child gives. Children also substitute and support each other: The greater the number of siblings with partners and the lower the frequency of sibling emotional support exchanges with a parent, the more care the child gives. The study reflects the various outcomes of sibling solidarity when older parents become dependent.

This article examines the effect that family structure has on the contact between older adults and their (step)children. A comparison is made among three family structures: biological families, complex stepfamilies, and simple stepfamilies. The sample consists of respondents aged 55 years or older from the “Living Arrangements and Social Networks of Older Adults in the Netherlands” survey of 1992. The contact between biological relationships and steprelationships is measured by means of two items: contact frequency and whether contact is perceived as regular and important. Parents have less contact with their biological children in stepfamilies compared with parents with their children in biological families. The contact with biological children is perceived as more often regular and important in biological families and complex stepfamilies compared with simple stepfamilies. No difference was found in the contact between stepparents and stepchildren in simple and complex stepfamilies. However, the contact with stepchildren is perceived as more often regular and important in simple stepfamilies in comparison to complex stepfamilies. It is not so much the difference between biological children and stepchildren that counts when studying the contact between (step)parents and (step)children, as what the structure of the aging (step)family is.

Using cross-sectional data from the Netherlands Kinship Panel Study (N = 1,231), this study examines the relationship between grandchildren and their grandparents across early adulthood. Age is used as a proxy for change during the grandchild's life course and the influence of major life course characteristics is examined. Results indicate that the majority of young adult grandchildren have contact with their grandparents, but the average frequency is low. Age differences in contact frequency suggest a decline in grandparent-grandchild contact across early adulthood. Multilevel analyses show that grandchildren's employment status, partner, and parenthood status do not affect contact frequency with grandparents. Rather, the results point at the importance of the parental home for facilitating grandparent-grandchild contact as age-related differences are accounted for by whether grandchildren left the parental home. Furthermore, most of the variance in grandparent-grandchild contact is attributable to differences between family of the mother's and family of the father's side.

Many current discussions of welfare state reforms focus on the 'young old', a group now generally perceived as healthy people past retirement age without a legal responsibility for dependent persons in need of care. For the welfare state, they constitute a resource whose activities are hard to steer. This article focuses on the influence of the welfare state on the number of 'young old' people. It describes different ways in which the welfare state influences the number of young old persons, and investigates whether variations in the regulations for the ages of normal, early and late retirement are the prime cause. The paper also estimates the share of the young old among those aged 50–90 years in 10 European countries in 2004 using comparable survey data. These shares ranged between 36 and 49 per cent for men and between 35 and 52 per cent for women. High shares were found in continental European countries, and low shares in Scandinavian countries and the United Kingdom. The shares in southern European countries varied among the countries and by gender. To explain the variations in the share, country differences in retirement regulations proved helpful but insufficient. When the overall influence of the welfare state on the share of young old persons in the population was analysed, a country-characteristic pattern emerged.

Using the convoy model (Kahn & Antonucci, 1980), this study examined the differential impact of
relocation, depending on the distance moved, on the size of three types of role networks. A total of 890 Dutch non-movers and 445 movers (aged 55 - 86) were selected from the Longitudinal Aging Study Amsterdam. Results of analyses of variance showed that the neighbor networks changed most after relocation. Long-distance movers discontinued the largest number of relationships with fellow club members. As expected, moving did not affect co-worker networks. The findings show that, consistent with the convoy model, role networks proved to be unstable. Older adults, however, restored their partial networks at the second observation by starting new relationships.

ISSN 1652-8670 [http://hdl.handle.net/1871/24345]

In this study, we examined life course events of older Dutch adults in relation to three types of moves and the moving distance. Using the frameworks developed by Litwak and Longino (1987) and Mulder and Hooimeijer (1999), we stipulated life events or triggers and conditions in various life domains. We selected a total of 1160 men and 1321 women (aged 54 to 91) from the Longitudinal Aging Study Amsterdam. We conducted multinomial logistic regression analyses to predict moves to a residential care facility, adapted housing or regular housing and to predict the moving distance. Retirement, an empty nest, widowhood and a decline in health each triggered specific moves. In additional analyses, the effects of triggers, especially health changes, were moderated by conditions. There is no indication of a specific trajectory of moves associated with consecutive life events, as suggested by Litwak and Longino. By combining triggers and conditions, however, the framework developed by Mulder and Hooimeijer allows for a more valid analysis.

ISSN 0167-9228 [http://hdl.handle.net/1871/39727]

Loneliness is an indicator of social well-being and pertains to the feeling of missing an intimate relationship (emotional loneliness) or missing a wider social network (social loneliness). The 11-item De Jong Gierveld scale has proved to be a valid and reliable measuring instrument for overall, emotional and social loneliness, although its length has sometimes rendered it difficult to use the scale in large surveys. In this study, we empirically tested a shortened version of the scale on data from two surveys (N = 9448). Confirmatory factor analyses confirmed the specification of two latent factors. Congruent validity and the relationship with determinants (partner status, health) proved to be optimal. The 6-item De Jong Gierveld scale is a reliable and valid measuring instrument for overall, emotional and social loneliness, which is suitable for large surveys.

Eenzaamheid wordt algemeen beschouwd als belangrijke indicator van sociaal welbevinden en betreft gevoelens verbonden aan het missen van een intieme relatie (emotionele eenzaamheid) en/of een tekort en gemis betreffende het bredere sociale netwerk (sociale eenzaamheid). De 11-item De Jong Gierveld schaal is uitgebreid getoetst op de multivariate en sociale eenzaamheid, maar ook voor emotionele en sociale eenzaamheid. De lengte van deze schaal vormde soms een bezwaar voor gebruik in grootschalige surveys. In deze studie is bekend dat de kwaliteit van een verkorte versie van deze schaal getoetst in nieuwe surveys (N = 9448).

Objectives: This study compares educational differences in the functional limitations of 55- to 65-year-olds in the Netherlands in 1992 and 2002 and examines whether changes are explained by cohort lifestyle and psychosocial changes. Methods: Data from two cohorts of 55-65-year-olds (n = 948 in 1992 and n = 980 in 2002) in the Longitudinal Aging Study Amsterdam are analysed. Results: Men's disability ratios are similar in both cohorts. The women's disability ratio is higher in 2002 than in 1992. In 2002 the male and female cohorts both report unhealthier behavior than in 1992. Multivariate logistic regression analyses show that adjusted for age, cohort, lifestyle and psychosocial resources, poorly educated men have higher odds of functional limitations than well-educated men (OR = 2.62, 95% CI = 1.57-4.37). Analyses among women show a significant interaction effect between education and cohort. Poorly educated women have higher odds of functional limitations in 2002 than in 1992 (OR = 3.33, 95% CI = 1.02-10.87). Conclusions: The results underscore the need for policies focused on improving the health and lifestyle of the poorly educated.

ISSN 0898-2643; eISSN 1552-6887

Objectives: This study examines the effects of own and spousal disability on social and emotional loneliness among married adults aged 65 and older. Method: Data from 710 men and 379 women of a Dutch community sample were analyzed with linear regression analyses. Results: For men, only their wives' disability was related to higher levels of social loneliness, whereas for women mainly their own disability was related to higher levels of social loneliness. Own disability and spousal disability were related to higher levels of emotional loneliness among both men and women. Effects of disability remained unaffected after controlling for characteristics of the social network and the marital relationship. Discussion: Findings underscore the importance of considering effects of both spouses' health on measures of individual well-being. Also, the traditional division of social roles makes older married men relatively vulnerable to social loneliness when their wives suffer from disability.

Er was eens een tijd dat gerontologen allemaal gerontologen waren en er een sterke band bestond met beleid en praktijk van het gerontologisch onderzoek. Maar in de latere jaren negentig tekenden zich veranderingen af. Specialisatie binnen de gerontologie nam toe en de band tussen wetenschap en praktijk werd losser. Een overzicht van deze ontwikkelingen binnen de sociale gerontologie en van daaruit de blik op de toekomst.

Differences in emotional well-being across several European regions have been observed for both loneliness and depression. These differences can be explained partly by individual characteristics, such as gender, age, marital status and household composition, and the support provided within relationships with kin and other members of the personal network. Previous research into loneliness adopted the view that variegating cultural values also contribute to the understanding of regional differences. In regions characterized by a family orientation, such as southern Europe, living alone is loneliness-provoking since people without a partner are expected to live with their families. In case of an individualistic orientation, such as in Northern regions, older adults without a partner prefer to live alone. With respect to regional differences in depression, no attempt has been made as yet to explain these from cultural values in society. The present paper presents an overview of regional differences in well-being and related characteristics and attempts to link these differences to societal values.

2007

Given the paucity of information on historical kin relations, this study uses survey data in order to investigate how family forms influenced the relationships among elderly siblings born in farming families between 1903 and 1937 in three regions of the Netherlands. In the area with stem families, impartible inheritance, and a custom of neighbor help, social networks are largest and contain more siblings. Multilevel analyses show that even when controlling for other factors, this particular family form positively affects contact frequency in sibling relationships. Our results not only show the persistence of differential kinship values. Since respondents’ networks were linked back to their families of socialization in the early twentieth century, findings also reflect regional disparities in kin relations in the past.

The personal networks of older people reflect their social opportunities and personal choices to maintain a specific set of relationships with relatives, neighbors, friends, acquaintances and so on. Network analysis is the method used to identify and examine the structural and functional features of the network of the older adult. The conceptualization and operationalization of the personal network depend on the subject of research. Five approaches to define personal network membership are presented and discussed. The five approaches differ regarding the part of the personal network that is mapped, and result in networks of different sizes and compositions. Regardless of the type of network delineation, a distinction can be drawn between the star network (data available on relationships with the focal person) and the full network (data available on all the network relationships). Features of the structure and content of both types of personal networks are presented. Finally, network analysis methods are presented and discussed, including ways to analyze hierarchical databases.

Ouderen met kleine netwerken van persoonlijke relaties waarin weinig familieleden en buurtgenoten zijn opgenomen, hebben een verhoogd risico voor sociale isolatie en psychische gezondheidsproblemen. Vooral 75-plussers, alleenstaande mannen, ouderen met een laag- economische status, die wonen in een grote stad behoren met name tot deze risicogroep. Ouderen die niet regelmatig steun uitwisselen met leden van hun netwerk, hebben een verhoogd risico op het ontberen van steun op latere leeftijd. Vorming en onderhoud van netwerken vindt tijdens de levensloop continu plaats; op latere leeftijd moet men 'oogsten' wat men eerder in het leven in relaties heeft geïnvesteerd. Informele zorg is een taak voor verschillende leden van het persoonlijk relatienetwerk, waarbij overleg moet plaatsvinden over afstemming en samenwerking. Eenzaamheid is het resultaat van een tekort schietend netwerk; er zijn onvoldoende relaties of men krijgt niet de ondersteuning die men zich wenst. Voorafgaand aan een interventie moet eerst de oorzaak van eenzaamheid achterhaald worden.

Background. The study investigates whether persons who have experienced childhood adversity are more likely to develop depressive symptoms when faced with recent events. Method. Data were used from a population-based sample, aged 55 to 85 years (*n* = 1887), which were not depressed at baseline. Childhood adversities and recent stressful life events were retrospectively assessed. Depressive symptoms were measured with the CES-D. Results. 14.4% of our sample experienced adverse events during childhood (< 18 yrs) and 35.4% experienced recent events. Associations of depressive symptoms were found with both, childhood adversity (OR 1.80, 95% CI 1.21–2.69) and recent life events (OR 1.42, 95% CI 1.01–2.00). The effect of recent events on depressive symptoms was not modified by childhood adversity. Limitations. Underreporting may...
be present due to unwillingness to report embarrassing events or to disclose painful memories. Conclusions. No evidence was found for the assumption that older persons were more vulnerable for depression in reaction to recent life events when they were exposed to childhood adversity.

Centraal in dit artikel staan de belangrijkste uitkomsten van een uniek evaluatieonderzoek naar eenzaamheidsinterventies bij ouderen. Recent zijn verspreid over Nederland achttien interventies uitgevoerd en van nabij gevolgd. Bij tien van deze interventies was het aantal deelnemers voldoende groot om het effect van de interventie op eenzaamheid kwantitatief vast te stellen. Bestrijding van eenzaamheid blijkt niet eenvoudig te zijn: bij slechts twee van de tien interventies is een daling van eenzaamheid onder de deelnemers waargenomen die zeer waarschijnlijk aan de interventie kan worden toegeschreven. Twee andere interventies hebben wellicht een preventieve werking gehad: terwijl de eenzaamheid toeneemt binnen de controlegroep, blijft de eenzaamheid onder de deelnemers over de tijd nagenoeg constant. Om inzicht te krijgen in de mogelijke oorzaken voor het uitblijven van een eenzaamheidsreductie onder de deelnemers bij de meerderheid van de interventies, is het effectonderzoek gevolgd door procesevaluaties. Dit heeft geresulteerd in een aantal lessen voor de toekomst die gehanteerd kunnen worden als een checklist wanneer een nieuw interventieproject wordt ontworpen.

This article focuses on the most important findings of a unique evaluation study of loneliness interventions among older adults. Eighteen interventions have recently been carried out and closely monitored in various parts of the Netherlands. In ten of these interventions the number of participants was sufficiently large to quantitatively determine the effect of the intervention on loneliness. It does not appear to be easy to overcome loneliness: no more than two of the ten interventions resulted in a reduction in loneliness among participants that may be attributed to the intervention. Two other interventions may have had a preventive effect: whereas loneliness increased among members of the control group, it remained more or less constant over time among participants. The effect measurements were followed by process evaluations in an effort to gain insight into the possible reasons why feelings of loneliness were not alleviated among participants in the case of most of the interventions. This resulted in a number of lessons for the future, which may be used as a checklist when designing new interventions projects.

The convoy model conceptualizes older adults’ networks of personal relationships as convoys of social support. This prospective study examined how contact and support in several relationships changed due to widowhood. Using observations between 1992 and 2002 from the Longitudinal Aging Study Amsterdam, multilevel models describe change in contact and support of 227 widowed and 408 married older adults. Contact and support were low before widowhood, and increased in all relationships after widowhood, and more so in child and sibling relationships. Around 2.5 years after widowhood, contact and support started to decrease. Our findings increase our understanding of the heterogeneity of network changes in old age and of the instability of the network as a social convoy in late life.

This study explains changes in contact frequency in relationships of the preseparation personal network in the early and later years after partners separate. The explanation includes general and separation-related characteristics of the network relationship and the individual. Personal interviews were conducted in three waves of a 12-year longitudinal study with 40 men and 64 women who separated in 1987 or 1988. Multilevel analyses on 1639 network ties showed that multiplex and kin relationships remained over the long term. Contact changes depended on network relationship characteristics, structural conditions, perceived restrictions, and alternative network relationships. Separation-related characteristics were more important in the early years, general characteristics in the later years after the separation.

http://dx.doi.org/10.1016/S1040-2608(07)12009-8
This study investigates whether the frequency of contact and support exchanged in relationships between parents and adult children declines over successive cohorts and over individual time in the Netherlands. Respondents included a birth cohort from 1928 - 1937 with data collected in 1992 (N = 941) and in 2002 (N = 574) and a birth cohort from 1938 - 1947 with data collected in 2002 (N = 884). We assessed cohort and time-sequential changes. Parents of the later cohort had more contact and support exchanges with their children than the earlier cohort, revealing that families have not declined in importance. Furthermore, longitudinally, contact and supportive exchanges with adult children decreased, suggesting that parents and children devote less time to intergenerational relationships during this 'empty nest' phase.

Eenzaamheid komt onder alle geledingen van de bevolking voor, bij jong en oud, zowel binnen als buiten de zorg. Het artikel geeft een overzicht van wat onder eenzaamheid verstaan wordt, wat er tegen te doen valt. De bijdrage is toegespitst op de zorg.

http://hdl.handle.net/1871/55577

Dit boek neemt de lezer in begrijpelijke taal mee langs de verschillende aspecten van eenzaamheid en levert duidelijke antwoorden op veel gestelde vragen. In deel 1 staat de begripsvorming centraal: Wat is eenzaamheid? Welke vormen kunnen we onderscheiden en hoe vaak komen die in ons land voor? Deel 2 behandelt de mogelijke verklaringen voor het feit dat mensen zich eenzaam voelen. Heeft dat te maken met het aantal vrienden en kennissen dat men heeft? Heeft dat te maken met de buurt waarin ze wonen? Welke risicogroepen zijn er? In deel 3 is er aandacht voor het voorkómen, oplossen en/of verwerken van eenzaamheid, waarbij nadrukkelijk wordt gekeken naar de bijdrage die mensen daaraan zélf kunnen leveren. Natuurlijk komen ook de mogelijke betekenis en invloed van de omgeving – familieleden, vrienden en kennissen – aan de orde, evenals de mogelijkheden van eenzaamheidsinterventies. Hoofdstukken:

‘Oude bomen moet je niet verplanten’ luidt een bekend spreekwoord en ook het ouderenbeleid voor wonen is op deze wijsheid geënt. Maar zijn ouderen die zelfstandig blijven wonen wel altijd beter af dan hun leeftijdgenoten die naar volledig bestemde woningen of woonvormen verhuizen? Bij een kleine groep ouderen met ernstige gezondheidsproblemen vermindert juist de eenzaamheid na een verhuizing naar een verzorgings- of verpleeghuis. Sommige oude bomen bloeien weer op.

Objectives. Gerotranscendence has been conceptualized as a potential development accompanying normal aging. Gerotranscendence is defined as a shift in metaperspective from a materialistic and pragmatic world view to a more cosmic and transcendent one. In the past decade, population-based studies have tested Tornstam's Gerotranscendence Scale. Its Cosmic Transcendence subscale, in particular, emerged as consistent. The aim of the present study was to examine (a) how cosmic transcendence relates to having a framework of meaning in life and (b) whether religiousness and demographic characteristics influence possible relationships. Methods. Participants were 928 older Dutch adults who responded to a questionnaire that included the Cosmic Transcendence Scale, aspects of religiousness and demographic characteristics. Results. A substantial, positive association between cosmic transcendence and framework of meaning in life was observed. This association was much more pronounced among participants who were less involved in religion, who were women, who were age 75 or older, or who were widowed. Discussion. The current study indicates that the personal relevance of cosmic transcendence depends on cultural factors such as secularization. Furthermore, cosmic transcendence seems to unfold as an important domain in the life view of women, the older old, and the widowed.

Loneliness is an indicator of social well-being and pertains to the feeling of missing an intimate relationship (emotional loneliness) or missing a wider social network (social loneliness). The 11-item De Jong Gierveld Loneliness Scale has proved to be a valid and reliable measurement instrument for overall, emotional, and social loneliness, although its length has sometimes rendered it difficult to use in large surveys. In this study, the authors empirically tested a shortened version of the scale on data from two surveys (N = 9,448). Confirmatory factor analyses confirmed the specification of two latent factors. Congruent validity and the relationship with determinants (partner status, health) proved to be optimal. The 6-item De Jong Gierveld Loneliness Scale is a reliable and valid measurement instrument for overall, emotional, and social loneliness that is suitable for large surveys.

Background. The loss of a spouse has been found to have a negative effect on physical and mental health and leads to increased mortality. Whether conjugal bereavement also affects memory functioning has largely been unexamined. The present study investigates the effect of widowhood on memory functioning in older persons. Method. The sample consisted of 474 married women and 690 married men aged 60–85 years in 1992, followed up in 1995 and 1998. During the study 135 (28%) of the women and 69 (10%) of the men lost their spouse. Linear regression analysis was used to examine whether widowed men and women differed from those who had not been widowed in rate of memory change over 6 years. Cross-domain latent-change models were subsequently used to evaluate the extent to which changes in memory are related to changes in other domains of functioning that may be affected by widowhood. Results. Older adults who lost a spouse during follow-up showed a greater decline in memory over 6 years than those who remained married. A higher level of depressive symptoms at baseline was related to lower levels of memory functioning and a greater decline. Memory decline was unrelated to changes in depressive symptoms and physical health. Conclusions. Loss of the spouse is related to a greater decline in memory in older adults. The absence of an association with physical functioning and the weak association with mental functioning suggest that losing a spouse has an independent effect on memory functioning.

This study examines loneliness and its correlates – health, residential care, partner status, and network size – over a seven-year period among adults born between 1908 and 1937. The four waves of data are from the Dutch ‘Living Arrangements and Social Networks of Older Adults’ and the ‘Longitudinal Aging Study of Amsterdam’ programs. Data from at least two waves are available for 2925 respondents. Results show that older adults generally become lonelier as time passes. The increase is greater for the oldest, the partnered, and those with a better functional capacity at baseline. Older adults who lose their partner by death show the greatest increase in loneliness. Not all older adults become more lonely: improvement in functional capacity and network expansion lead to less loneliness. Entry into residential care does not affect loneliness. The longitudinal design provides new insights into factors that protect against loneliness compared to cross-sectional studies.

In toenemende mate worden in woonzorgcentra initiatieven ondernomen om de eenzaamheid van bewoners aan te pakken. Of deze interventies ook echt effectief zijn, is niet duidelijk. Reinoud Adviesgroep en WoonZorgAdvies zijn in 2002 met het project ‘Aanpak van eenzaamheid onder ouderen in woonzorgcentra’ begonnen, met financiële ondersteuning van Stichting Sluyterman van Loo. In een eerder nummer van Gerôn is ingegaan op de opzet van het project. In dit artikel komen de belangrijkste uitkomsten van de evaluatie en het effectonderzoek aan bod.

http://hdl.handle.net/1871/18937

Eindrapportage aan de Stichting Sluyterman van Loo van een vergelijkend effect- en procesevaluatieonderzoek naar interventies ter voorkoming en vermindering van eenzaamheid onder ouderen.

In this study we apply a lifecourse perspective to an examination of older adults’ attitudes about gender roles and moral issues. The study goes beyond previous research in that it examines the relationships between older adults' attitudes and: (a) experiences in the parental home, (b) people’s own marital and work experiences through the entire lifecourse, and (c) the marital and work experiences of their children. The sample consists of respondents aged 55 or more years from the ‘Living Arrangements and Social Networks of Older Adults in The Netherlands’ survey of 1992 and the ‘Longitudinal Ageing Study Amsterdam’. It is shown that a large majority of older adults subscribe to the view that people have the freedom to make their own choices about the issues of voluntary childlessness, abortion and euthanasia. Similarly, most older adults favour equality between men and women. Multivariate analyses show that people’s attitudes are generally consistent with their lifecourse experiences. It is found that unconventional lifecourse experiences, particularly with respect to childbearing, associate with more progressive attitudes in late life. The behaviour and lifecourse experiences of their children are also related to older adults’ attitudes. Particularly, if their children co-habited, older adults tend to be more progressive. These findings suggest that an important mechanism by which societal change may have affected older adults is through their children’s experiences.

Objective: To develop a hierarchical scale that measures activity limitations in walking in patients with lower-extremity disorders who live at home. Design: Cross-sectional study. Setting: Orthopedic workshops and outpatient clinics of secondary and tertiary care centers. Participants: Patients (N=981; mean +/- age standard deviation, 58.6 +/- 15.4y; 46% men) living at home, with different lower-extremity disorders: stroke, poliomyelitis, osteoarthritis, amputation, complex regional pain syndrome type 1, and diabetic and degenerative foot disorders. Interventions: Not applicable. Main Outcome Measures: (1) Fit of the monotone homogeneity model, indicating whether items can be used for measuring patients; (2) fit of the double monotonicity model, indicating invariant (hierarchical) item ordering; (3) intratest reliability, indicating repeatability of the sum score; (4) robustness, addressing the clinimetric properties within subgroups of patients; and (5) differential item functioning, addressing the validity of comparisons between subgroups of patients. Results: Thirty-five of 41 dichotomous items had (1) good fit of the monotone homogeneity model (coefficient H=.50), (2) good fit of the double monotonicity model (coefficient H^T=.33), (3) good intratest reliability (coefficient rho=.95), (4) satisfactory robustness (within subgroups of patients defined by age, sex, and diagnosis), and (5) some differential item functioning (6 items in amputees compared with nonamputees). Conclusions: A hierarchical scale, with excellent scaling characteristics, was developed to measure activity limitations in walking in patients with lower-extremity disorders who live at home. The measurements should be interpreted cautiously when making comparisons between amputees and nonamputees.

This study focused on two conceptually distinct measures of the filial responsibility expectations of older adults: a vignette technique and an attitude item scale. Data were based on 1,553 respondents aged 61 to 92 years who participated in the Longitudinal Aging Study Amsterdam in 1998 to 1999. The results showed that the item scale had multiple dimensions of filial expectations. Older adults distinguished between emotional-, instrumental-, contact-, and information-oriented expectations. The vignette technique resulted in a unidimensional measurement of expectations. The intercorrelation between the scores of the item scale and vignette technique was modest, indicating a certain amount of overlap. Child characteristics incorporated into the vignettes added to the specificity of measurements of the filial expectations. The authors observed that older adults were more likely to have expectations for care from an adult child who is not employed and does not have children. Minor differences between sons and daughters were observed.

http://hdl.handle.net/1871/33752  
The effects of cognitive and physical decline on changes in the size and composition of four types of personal networks over a period of six years were investigated in a Dutch sample of 1552 older...
adults, aged 55–85 years. The effects of age and a decline in cognitive and physical functioning on
the probability of changes in all possible network types were investigated. Transitions related to
age and to cognitive and physical decline were observed for about one-third of the study sample.
Greater age was associated with an increase in the number of family members in the network.
Physical decline was associated with a replacement of friends and neighbors by family members
only if the network was large. In small networks, no such association occurred. Cognitive decline
was associated with a loss of relationships, most likely friends and neighbors, who were not found
to be replaced by family members. Physical decline appears to be associated with an increase in
the potential number of supporters in the network, whereas cognitive decline is associated with a
decrease in the number of potential supporters.

Background and Aims: Some prospective studies show that depression is a risk factor for cognitive
decline. Thus far, the explanation for the background of this association remained unclear. In the
present study it is investigated (1) whether depression is etiologically linked to cognitive decline; (2)
whether depression and cognitive decline may be the consequence of the same underlying
subcortical pathology, or (3) whether depression is a reaction to global cognitive deterioration.
Methods: A cohort of 133 depressed and 144 non-depressed older persons, was followed at eight
successive observations during three years. All subjects were participants of the Longitudinal
Aging Study Amsterdam (LASA). Depression symptoms were measured by means of the CES-D at
eight successive waves. Cognitive function (memory function, information processing speed and
global cognitive functioning) was assessed at baseline and at the last CES-D measurement.
Results: Our results show that the severity and duration of depressive symptoms were not
associated with subsequent decline in memory functioning or global cognitive decline. There was
an association between both chronic mild depression and chronic depression, and decline in speed
of information processing. Conclusions: These results support the hypothesis that in older persons
chronic depression as well as cognitive decline may be the consequence of the same underlying
subcortical pathology.

Measuring activity limitations in climbing stairs: Development of a hierarchical scale for patients
with lower-extremity disorders living at home. Archives of Physical Medicine and Rehabilitation, 85,
967-971.
http://dx.doi.org/10.1016/j.apmr.2003.11.018
http://hdl.handle.net/1871/26143

Objective. To develop a hierarchical scale that measures activity limitations in climbing stairs in
patients with lower-extremity disorders living at home. Design. Cross-sectional study with Mokken
scale analysis of 15 dichotomous items. Setting. Outpatient clinics of secondary and tertiary care
centers. Participants. Patients (N = 759; mean age +/- standard deviation, 59.8 +/- 15.0y; 48% men)
living at home, with different lower-extremity disorders: stroke, poliomyelitis, osteoarthritis,
amputation, complex regional pain syndrome type I, and diabetic foot problems. Interventions. Not
applicable. Main outcome measures (1) Fit of the monotone homogeneity model, indicating
whether items can be used for measuring patients; (2) fit of the double monotonicity model,
indicating invariant (hierarchical) item ordering; (3) intratest reliability, indicating repeatability of the
sum score; and (4) differential item functioning, addressing the validity of comparisons between
subgroups of patients. Results. There was (1) good fit of the monotone homogeneity model
(coefficient H = .50) for all items for all patients, and for subgroups defined by age, gender, and
diagnosis; (2) good fit of the double monotonicity model (coefficient HT = .58); (3) good intratest
reliability (coefficient [rho] = .90); and (4) no differential item functioning with respect to age and
gender, but differential item functioning for 4 items in amputees compared with nonamputees.
Conclusions. A hierarchical scale, with excellent scaling characteristics, has been developed for
measuring activity limitations in climbing stairs in patients with lower-extremity disorders who live at home. However, measurements should be interpreted with caution when comparisons are made between patients with and without amputation.

This study first identified types of change in the size of the personal network over a period of 12 years following divorce. Second, differences in network change were explained by taking into account divorce characteristics, personal capacities, and structural conditions. Personal interviews were conducted in three waves of a 12-year longitudinal study with 40 men and 64 women who divorced in 1987 or 1988. Most divorcees experienced network losses shortly after the divorce and in half of the cases these losses were not compensated for in the later years after divorce. For some, divorce brought merely network gains, albeit in the longer term. Personal capacities and structural conditions did not differ significantly across participants in different types of network change. Characteristics of the divorce (attitude toward divorce and conflicts with the ex-partner after divorce) partly explained differences in network change after divorce.

Loneliness is experienced in many cultures. To properly assess cross-cultural differences, attention should be paid to the level, determinants and measurement of loneliness. However, cross-cultural studies have rarely taken into account more than one of these. Differences in the level of loneliness were hypothesized on the basis of national differences in partnership, kinship and friendship, which were assumed to be related to cultural standards within a society. Differences were examined among married and widowed older adults aged 70 to 89 years living independently in the Netherlands (N = 1847), Tuscany, Italy (N = 562) and Manitoba, Canada (N = 1134). Loneliness was measured with an 11-item scale. The Manitobans were high on emotional loneliness and the Tuscans were high on social loneliness. Partner status excepted, the determinants were nearly the same across the three locations. Differential item functioning (DIF) related to the three locations was observed for most items. Interactions with gender and the availability of a partner relationship were observed.

Objectives. Global social support measures have been shown to be related to several health outcomes, but little is known about the effects of different social ties and their support on the risk for decline in physical functioning among older people without as compared to those with chronic diseases. This study examines whether different types of social ties and support differentially mitigate the negative effects of chronic diseases on decline in physical functioning. Methods. Using data from two cycles of the Longitudinal Aging Study Amsterdam (N = 2357), logistic regression analyses adjusted for baseline functioning, age, gender, and incidence of chronic diseases were conducted to assess the effect of different social ties for subgroups with different numbers of chronic diseases. Information about presence of different social ties included partner status and numbers of daughters, sons, other family members and non-kin relationships. Social support
included instrumental and emotional support and the experience of loneliness. Decline in physical functioning was determined by substantial change after three years on a 6-item self-report scale. Results. Having a partner had a protective effect on decline in physical functioning in people without chronic diseases at baseline, but this was not found for those with chronic diseases. Total network size had an adverse effect in older people without chronic diseases, but a positive effect when chronic diseases were present. This was mainly due to a positive effect for the number of daughters and non-kin relationships. Discussion. Our results provide evidence that different types of social relationships and the support they provide differentially influence the risk for decline in physical functioning in older people with or without a chronic disease.

This paper examines the impact of childhood and adulthood socio-economic status (SES) on personal network characteristics in later life. Data are derived from 2,285 married older adults (born between 1903 and 1937) who participated in face-to-face interviews for the Dutch survey on ‘Living arrangements and social networks of older adults’ conducted in 1992. Childhood and adulthood SES were indicated by the father’s and own level of education and occupation. Multivariate analyses showed that SES in adulthood has more impact on network features in old age than father’s SES. People with lifetime low SES or with downward SES mobility had small networks, low instrumental and emotional support from non kin, but high instrumental support from kin when compared with the upwardly mobile or those with high lifetime SES. The level of education was a better indicator of network differences than occupational prestige. It is concluded that obtaining a high SES during life pays off in terms of having more supportive non kin relationships in old age. The small networks and less supportive non-kin relationships of low status older adults make them more vulnerable to situations in which kin are unavailable or less willing to provide support. This study underscores the distinction between types of support and types of relationships in the SES – network association. Further research on the social pathways of socio-economic inequality of health and wellbeing should take these distinctions into account.

Relationships with neighbors are considered exchange relationships, in which the continuation of exchanges depends on balance in previous exchanges. Our study tested whether this is the case. An exchange relationship implies that neighbor relationships are isolated units. We expected, however, that neighborhood integration also affects the continuation of exchange among neighbors. Data were from a longitudinal study among 1,692 independently living Dutch adults of ages 55 to 85 years at baseline and their 7,415 relationships with proximate network members. At
a four-year follow-up, both perceived balance and neighborhood integration at baseline increased the chance of instrumental support exchange occurring. We concluded that it is too limited to view relationships between neighbors as exchange relationships, as these relationships are embedded in larger communities, where such communities exist.

Retirement is an important life cycle marker and has a major impact on an individual's functioning. Based upon the social convoy model, it is hypothesized that retirement decreases the likelihood of continuation of coworker relationships. Socio-emotional selectivity theory predicts a decline in the number of peripheral relationships with aging and thereby in network size and number of coworker relationships among working and retired people. Data comes from the Longitudinal Aging Study Amsterdam with five observations between 1992 and 2002. At baseline 226 men aged 54-81 years were employed; 166 men retired in the course of the study. The results of multilevel regression analyses showed a stable network size both for working and retired men. Among all men the number of work-related network members declined, but more strongly among retirees. It is concluded that the convoy model fits better with the data than socio-emotional selectivity theory.

http://dx.doi.org/10.1093/geronb/57.2.P153
http://hdl.handle.net/1871/39717
The impact of three types of everyday activities (i.e., social, experiential, and developmental) on four cognitive functions (i.e., immediate recall, learning, fluid intelligence, and information-processing speed) and one global indicator of cognitive functioning (Mini-Mental State Exam score) over a period of 6 years was studied in a large 55-85-year-old population-based sample (N = 2,076). A cross-lagged regression model with latent variables was applied to each combination of 1 cognitive function and 1 type of activity, resulting in 15 (3 x 5) different models. None of the activities were found to enhance cognitive functioning 6 years later when controlling for age, gender, level of education, and health, as well as for unknown confounding variables. Conversely, one cognitive function (i.e., information-processing speed) appeared to affect developmental activity. It is suggested that no specific activity, but rather socioeconomic status to which activities are closely connected, contributes to maintenance of cognitive functions.

http://hdl.handle.net/1871/39716
This study addresses the relation between attrition and characteristics of the study protocol, specifically contact frequency, and respondent burden. The study is based on data from a longitudinal study with side studies on various topics, so that respondents have differential
exposure to these study characteristics. Attrition outcomes are refusal and ineligibility through frailty. The effect of side study contact frequency and respondent burden on these outcomes is examined in two analytical samples: (1) baseline participants surviving to the first follow-up after 10 months (sample I), and (2) first follow-up participants surviving to the second follow-up after 3 years (sample II). Attrition during the first study interval was higher than during the second study interval, 15.5 and 5.4%, respectively. In sample I, the request to participate in a side study on social network implied an increased risk of refusal to participate at first follow-up if subjects refused the request (RR 8.34). However, if subjects participated in the network study, their risk of refusal was decreased (RR 0.42). In sample II, requests to participate in one to four side study cycles increased the risk of refusal to participate at second follow-up if subjects participated in fewer cycles than requested (RR 9.21). If subjects participated in all side study cycles that they were approached for, even if the number of cycles was five or more, this had an opposite effect: it decreased the risk of refusal (RR 0.18). Ineligibility was not significantly associated with contact frequency or respondent burden. Furthermore, neither contact frequency nor respondent burden related refusal was selective with respect to socio-demographic characteristics and physical and mental health indicators. It is concluded that contact frequency is nonlinearly associated with attrition. The findings further suggest that designing a series of side studies within the "longitudinal paradigm" does not severely damage the study's validity in terms of selective attrition.

A negative effect of good health on the instrumental support received can be viewed as an effect of the mobilization of helpers. A positive effect of good health on the personal network size and the instrumental support given demonstrates that people in poor health have difficulty actively maintaining their relationships. Furthermore, the support received and given is positively related to the support given and received in the past. In four waves of a seven-year longitudinal study, personal interviews were conducted with 2,302 older Dutch adults (aged 60 to 85) who live on their own. The hypotheses have been confirmed. An implication is that investing in relationships by giving support might pay off in times of need.

2001

The study explains differences in the support network and social participation of divorced men and women by taking into account partner status, current living conditions, characteristics of the disrupted marriage, and personality. A sample of 722 men and 1073 women, divorced between 1947 and 1997 in the Netherlands, participated in a survey conducted in 1998. Support networks of single women contained the largest proportion of kin and the smallest proportion of post-divorce contacts. Single men had the least kin and men living with a new partner had the most post-divorce contacts. Compared to single men and women those living with a partner had higher rates of social participation. Multivariate regression analyses indicated that, for both men and women, differences in network features and social participation after divorce were best explained by current structural conditions (availability of a partner, level of education, employment and child care), and to a lesser degree by characteristics of the disrupted marriage (overlap in marital networks) and by one’s personality (extraversion).

Divorce is a life transition that is attended by major changes in the structure of the personal network. This study is aimed at (1) describing differences in the number of emotional and instrumental supportive relations between married, divorced, and remarried men and women in the Netherlands, and (2) explaining these differences by taking into account differences in extraversion and emotional stability. Cross-sectional data were analyzed on supportive relations of a representative sample of 2346 married and divorced (single as well as remarried) men and women who participated in a large survey conducted in the Netherlands in 1998-1999. Results show that the divorced who remained single had the largest support networks. Networks of the married and remarried comprised equal numbers of supporters. Personality characteristics offered a relatively small though unique contribution to the explanation of differences in the number of supporters. Respondents high in extraversion had a relatively large number of emotional and instrumental supporters. The emotionally stable had relatively small numbers of emotional supporters and the emotionally stable divorced relatively large numbers of instrumental supporters.

The procedure of standardized repeated measurement, as used in panel studies, may hamper the quality of the data, due to the potential ‘reactivity’ of survey interviewing on respondents’ attitudes and behavior. In case respondents are interviewed in subsequent waves by different interviewers, differential interviewer effects may occur. These threats to data quality are illustrated with data from a longitudinal study among 2,819 older adults, conducted in The Netherlands. From an analysis of 100 interview protocols it appears that the behavior of the interviewers has a significant impact on the data obtained. Interviewers seem to adjust their interviewing strategy, on the one
hand to a norm regarding a 'normal' personal network, and on the other hand to a norm about the appropriate interviewing time. Suggestions are formulated to prevent misestimating of actual change within respondents over time leading to incorrect conclusions about causal relationships.

In order to promote well-being and alleviate loneliness among older women, a course was developed to help them improve or develop new friendships. Thirty-two participants in the course were interviewed on their friendships and loneliness at two points in time, immediately following the course and a year later. Loneliness scores were compared to those of a matched control group. Both groups were very lonely initially and demonstrated a significant reduction in loneliness a year later. However, more women in the friendship course were successful in reducing their loneliness; a majority had made new friends, slightly less than half had improved existing friendships. There was a significant increase in the complexity of their friendship networks following the course.

The effects of four social-structural neighbourhood characteristics on the relative size and the composition of neighbouring networks are tested in a sample of 3,504 older adults born between 1908 and 1937 and living in three regions in the Netherlands. Interactions with individual income and ADL capacity are included in multilevel regression analyses, to test effects of older adults' environmental dependency. Population density and residential mobility both have a negative effect on the relative size of neighbouring networks, and the effect of urbanisation is strongest among poorer respondents. These findings suggest first that the structural effects of urbanisation work at the level of concentration vs. dispersion of personal networks, and second that there is no general mechanism of environmental dependency.

The aim of the research is to assess whether there is change in the size and composition of older adults' personal network. Furthermore, change in contact frequency and received instrumental support within the relationships is studied. Five relationship types are distinguished: children, other kin, friends, neighbors and acquaintances. Older adults with a decline in physical capacity are

Publications by Theo van Tilburg, p. 49
compared with those with stable and increased capacities. Furthermore, differences according to (change in) partner status and age are investigated. Data are from the Longitudinal Aging Study Amsterdam, including the first and fourth observation of 1634 older adults living independently. The observation interval is 7 years. A decline in physical capacities is observed for 35% of the older adults, the capacities are stable for 60% and an increase is observed for 5%. In general, network size and composition did not change. The frequency of contact within the relationships decreased. Decline was high for parent-child relationships, but relatively low among older adults who faced a moderate to strong physical decline. Among older adults who did not have a partner at the fourth observation and among the oldest the frequency of contact with children increased independent from the degree of physical decline. The decline in contact with neighbors was nearly absent for older adults who faced a moderate to strong physical decline; the contact increased when there was no partner at the fourth observation. The instrumental support received increased within all relationship types, independent from the degree of physical decline. It is concluded that research into determinants of the decline in parent-child contacts is needed and that the meaning of neighbors should receive attention.

The question of interest is whether differences between regions, rural and urban communities and neighbourhoods contribute to older adult loneliness, when their health and social circumstances are also taken into account. The data are from nine research projects involving older persons in several regions in the Netherlands. Six were carried out by Community Health Departments (GGD’s) in 's-Hertogenbosch, Oss, Drenthe, Nijmegen, the Achterhoek and in the city triangle Apeldoorn-Deventer-Zutphen. Three other data sets are from the NESTOR-program ‘Living arrangements and social networks of older adults’ (LSN), in which older adults in Amsterdam and surroundings, Zwolle and surroundings and Oss and surroundings, participated. The LSN-respondents were distinguished by region, leading to three sub-populations (LSN-West, LSN-East and LSN-South). Multivariate multilevel regression analysis show that, controlling for the health and social circumstances of the older adults, regional differences in loneliness are small, and that living in an urbanised area and in a neighbourhood with relatively few older people, contributes to more intense feelings of loneliness.

Value studies indicate that the process of individualization in Europe started in Sweden and Norway, and continued via France and the Netherlands; the southern European countries lag behind, and are still characterized by more traditional family orientations. Starting from this point of view, this paper investigates the effects of differences between the Netherlands and Italy in the field of living arrangements of older adults with and without partners. The consequence of living alone and of coresidence with adult children have been further investigated, using loneliness as the dependent variable. The size and support functions of the network of social relationships, socioeconomic resources, health, sex and age are also taken into account. Data come from face-to-face surveys among a random sample of older adults (55 to 89 year old women and men) in the Netherlands (N = 4,494) and in Italy (N = 1,570), using the same research design and questionnaire. The data show country-specific differences in household types of older adults: The proportion living alone is much higher among older people without partners in the Netherlands; the
proportion coresiding with their adult children is higher in Italy than in the Netherlands. Controlling for age, health, sex, size and support of the network, and for differences in socioeconomic resources, household composition is still the most important determinant of loneliness. Living without a partner in the same household as one's adult children yields country-specific correlations that correspond with differences in value orientations: less loneliness in Italy, more loneliness in the Netherlands.

Exchange theory assumes that people prefer balanced support exchanges in their relationships. If there is an imbalance and no expectation of change in the future, a relationship might be terminated. The question is which relationships are discontinued. The data are from a longitudinal study of 2,057 older adults who identify 18,915 relationships at T1. A relationship is regarded as discontinued if it is not identified by the older adult at the second and third measurement moments. Of the T1 relationships, 4,042 have since been discontinued. The results of a multilevel logistic regression analysis show that the more intensive the support exchanges are at T1, the more likely it is for relationships to be continued. Relationships where older adults are overbenefited with instrumental support, i.e. receive more than they give, have a higher chance of being continued. However, if older adults are overbenefited with emotional support, this decreases the chance of the relationships continuing. The type of relationship has a significant effect on whether or not it is continued. Close kin relationships are most likely to be continued, and relationships with less close kin, friends and neighbors have a higher chance of being discontinued. The costs of the relationship are also decisive; the higher the contact frequency and the lower the traveling time to the network member, the higher the chance of the relationship being continued. Furthermore, the larger the network of the older adult, the more likely it is for an unbalanced relationship to be discontinued.

If the norm of filial responsibility is apparent, children should give relatively much instrumental support to their parents. Structural circumstances of adult children such as being employed or having young children, and of their parents such as having small families influence the amount of instrumental support the elderly parents receive. Data are from a sample of 365 elderly adults and 634 of their children. The higher the filial responsibility of both parent and children, the more support the parent receives. Mothers, old parents, parents in need of support and without a partner receive relatively much support. The structural circumstances of the children do not have any effect on parent’s receipts. Reciprocity is an important determinant of the support the parent receives.

Publications by Theo van Tilburg, p. 51
Objective: This study examines whether patterns of social network size, functional social support and loneliness are different for older persons with different types of chronic diseases. Methods: In a community-based sample of 2,788 men and women aged 55 to 85 years participating in the Longitudinal Aging Study Amsterdam, chronic diseases status, social network size, support exchanges and loneliness were assessed. Results: Social network size and emotional support exchanges were not associated with disease status. The only differences between healthy and chronically ill people were found for receipt of instrumental support and loneliness. Disease characteristics played a differential role: higher feelings of loneliness was mainly found for persons with lung disease or arthritis, and receiving more instrumental support was mainly found for persons with arthritis or stroke. Discussion: The specifics of a disease appear to play a (small) role in the receipt of instrumental support and feelings of loneliness of chronically ill older persons.

Changes in the networks and the health of a general sample of 2,903 Dutch older adults were studied, based on three observations with a total time span of four years. The better the functional capacity and the self-rated health of the old people, the larger their network was, the less instrumental support was received from their network members, and the more instrumental support was given. The positive effect of poor health on instrumental support received can be considered as an effect of the mobilization of helpers. The negative effect of poor health on instrumental support given, reflects the fact that people in poor health have difficulty in actively maintaining their relationships. Both tendencies affect the network size in different directions, which might be a reason for the relatively small effect of health on the network size. An extended version is published as: Van Tilburg, T.G. (1998). Changes over time in the personal networks and health of older adults. In D.J.H. Deeg, A.T.F. Beekman, D.M.W. Kriegsman, & M. Westendorp-de Serière (Eds.), *Autonomy and well-being in the aging population II: Report from the Longitudinal Aging Study Amsterdam 1992-1996* (pp. 123-140). Amsterdam: VU University Press.

This article focuses on the cutting scores for the measurement of loneliness on the Loneliness Scale (De Jong Gierveld & Kamphuis, 1985). A cutting score is used to distinguish the lonely from the not lonely. Data have been analyzed relating to interviews with 3,823 respondents (54-89 years old) who live independently. Use has been made of the individuals' self-assessed level of loneliness. More than would be the case with arbitrary cutting scores, this is in keeping with the individuals' own perception. The figures show that 68% of the elderly persons in the Netherlands are not lonely, 28% are moderately lonely, and 4% are quite lonely. Previous research used a lower cutting score and, consequently, observed that much more people are lonely.

Gerotranscendence has been defined as a shift in meta-perspective, from a materialistic and rationalistic perspective to a more cosmic and transcendent one that accompanies the process of aging. The present study describes scale characteristics of the Dutch translation of Tornstam’s gerotranscendence scale, using data from a sample among adults aged 56-76 years (N=556). Two subscales evolve from scale analysis, similar to those found by Tornstam: cosmic transcendence and egotranscendence. Scores on both subscales are higher for the older old, as well as for the unmarried, divorced or widowed respondents who suffer from physical impairments. Scale scores are also higher for respondents with depressive complaints. On the subscale cosmic transcendence Roman Catholics have higher scores than Protestants and non-church members. On the subscale egotranscendence well educated respondents and those with few social contacts have higher scores than persons with less education and those with many contacts. The strength of the associations is modest and the variance explained is small. The findings warrant further research into the question whether gerotranscendence adds to competence in later life.

Exchange theory assumes that people strive towards a balance in their personal relationships. The question is why the balance is not restored in unbalanced relationships where older adults receive more instrumental support than they give. The data are from a longitudinal study of 408 older adults and 2044 of their network members. At T1, the older adults received more instrumental support than they gave in 335 (17%) of their relationships. The instrumental support balance in these relationships at T1 was also assessed. The results of a multilevel regression analysis show that network members continue giving support to older adults who are in poor health. If the network member is in poor health, the balance is likely to be restored. Four other reasons for continuing the imbalance were also examined. No evidence was found to back the idea that a lack of instrumental reciprocity could be compensated by the older adults giving more emotional support. The second hypothesis (that close relationships often involve social norms that make it difficult to withdraw from un reciprocated support giving) was confirmed: in kin relationships and friendships, the imbalance persisted over time, while neighbor and other non-kin relationships returned to balance. Thirdly, it was hypothesized that if there were a small number of alternative supporters, it would be hard to withdraw from un reciprocated support giving. However, it was found that if the network was small, the imbalance was not likely to endure. Finally, as predicted, if there was generalized network reciprocity, the balance in particular relationships was not restored.

This article presents an overview of the design and results of the NESTOR survey 'Living Arrangements and Social Networks of Older Adults', an empirical study, started in 1992, among a representative sample of 4494 people, aged 55-89, selected from the population registers of 11 municipalities in the Netherlands. Questions were asked about living arrangements, the composition and functions of social networks, and important transitions in the marital, parental and occupational careers. The results indicated a wide diversity in living arrangements and social networks, a diversity which is particularly visible among the young old. They not only have larger networks, but are also more likely to live alone, to be divorced and to participate in shared housing arrangements. The networks vary considerably in size, from 0 to more than 40 important relationships. The decrease in network size with age appears to be directly related to specific life events such as widowhood, physical handicaps, residential moves etc. About 2/3 of the relationships are family relationships: parents, children (in law), grandchildren (in law), brothers and sisters (in law), uncles and aunts. Older people tend to be in touch at least once a month with the majority of close family members. The intensity of supportive exchanges (giving and receiving instrumental and emotional support in the twelve relationships with the highest levels of contact) is moderate, however mostly in balance. Only the very old receive somewhat more instrumental support and give considerably less than the 'young-old'. We studied the shift in balance between giving and receiving over a period of 12 months among a small proportion of the sample, checking a central hypothesis of exchange theory. In some cases a new balance evolves. In others the relationship continues to exist for a number of reasons, despite the imbalance. Early life experiences appear to be important for later life outcomes. Those who experienced the divorce of their parents before the age of 15 or those whose parents lived apart permanently (e.g. unmarried mothers) have a smaller social network and feel more lonely. Marital history has an impact on patterns of informal and formal care. E.g., those respondents without a partner who have children are less likely to use formal care than those who are childless. Among divorced elderly the use of formal care not only varies between men and women but also differs according to the marriage in which the children are born, first or second marriage. Occupational history is strongly related to the income level of older women living alone.

Effects of psychosocial coping resources on depressive symptoms were examined and compared in older persons with no chronic disease or with recently symptomatic diabetes mellitus, lung disease, cardiac disease, arthritis, or cancer. The 719 persons without diseases reported less depressive symptoms than the chronically ill. Direct favorable effects on depressive symptoms were found for having a partner, having many close relationships, greater feelings of mastery, greater self-efficacy expectations, and high self-esteem. Buffer effects were observed for feelings of mastery, having many diffuse relationships, and receiving emotional support. Buffer effects were differential across diseases for emotional support (in cardiac disease and arthritis only) and for diffuse relationships (in lung disease). Receiving instrumental support was associated with more depressive symptoms, especially in diabetes patients.

Objectives. Previous studies have shown that most older people have a significant number of relationships. However, the question of whether the aging of old people produces losses in their personal network remains open for discussion. This study models the individual variability of the changes affecting multiple personal network characteristics. Methods. Personal interviews were conducted with 2,903 older Dutch adults (aged 55-85) in three waves of a four-year longitudinal study. Results. A stable total network size was observed, with an increasing number of close relatives and a decreasing number of friends. Contact frequency decreased in relationships, and the instrumental support received and emotional support given increased. Age moderated the effect of time for some of the network characteristics and for many of them, effects of regression towards the mean were detected. Furthermore, major variations in the direction and the speed of the changes were detected among individual respondents, and non-linear trends were observed. Discussion. The widely varying patterns of losses and gains among the respondents squares with the focus on the heterogeneity of developments among aging people. The instability of the network composition might reflect the natural circulation in the membership of networks.

Methods for delineating personal networks in surveys contain complex instructions for the interviewers. It is assumed that the interviewers’ experience and education influence their ability to follow these instructions. The magnitude of the interviewer effects on the personal network size has been investigated, and differences among interviewers have been explained on the basis of their experience and education. The data are from a survey among 4,059 older adults in the Netherlands interviewed in 1992 by 87 interviewers. A strong interviewer effect was observed. Furthermore, the results of a multilevel regression analysis showed that, controlled for respondent characteristics, well-educated interviewers with minor experience prior to the project and major experience within the project (i.e. the high sequence number of the interview) generated relatively large networks.

*Publications by Theo van Tilburg, p. 55*

On the average, older adults in Italy are lonelier than those in the Netherlands. The results of a study by Jylhä & Jokela (1990) showed that loneliness was more prevalent in regions of Europe where living alone was rarest and where community bonds were strongest. This inverse macro-level association, an increasing proportion of lonely older people and a decreasing proportion of older people who live alone from northern to southern Europe, could not be explained by differences in individual social integration. The aim of the current study was to reinvestigate this association. The data were from surveys conducted in the Netherlands (N = 3,750) and northwestern Tuscany, Italy (N = 1,543). Fewer older adults lived alone in Tuscany than in the Netherlands, indicating that the Dutch were less integrated. As regards their participation in social organizations and personal networks, the Tuscan older adults were less integrated. To a large extent, loneliness among the Dutch and Tuscans based on differences in social integration could be similarly explained, and regional loneliness differences could be attributed to individual situations and characteristics.

1997

Studied depression at the syndrome level and at the diagnostic level in a large random sample of older adults as part of the Longitudinal Aging Study Amsterdam (Deeg et al, 1993). Human Ss: 3,056 male and female Dutch middle-age, old, and very old adults (aged 55-85 yrs) (major depression in some Ss) (residents of 3 regions of the Netherlands). Ss were interviewed. A 2-stage screening procedure was used to diagnose depression. The Diagnostic and Statistical Manual of Mental Disorders-III (DSM-III) criteria for major depression were used. Tests used: The Center for Epidemiologic Studies Depression Scale, the Diagnostic Interview Schedule; National Institute of Mental Health and the Mini-Mental State Examination.

Examined the association between religious involvement and depression in older Dutch citizens, focusing on models of the mechanism in which religious involvement impacts other factors related to depression. Ss were 2,817 older adults aged 55-85 years living in the community who participated in the Longitudinal Aging Study Amsterdam. Depressive symptoms were assessed using the Center for Epidemiologic Studies Depression Scale, and religious involvement was assessed using items on frequency of church attendance and strength of church affiliation. Further data were collected on physical health, size of social network, social support, sense of mastery, and self-esteem. As in North American studies, religious involvement appeared to be inversely associated with depression, both on symptom and syndrome levels. Controlling for sociodemographics, physical impairment and network support did not substantially affect this association, particularly among 75-85 year old Ss. The inverse association between religious involvement and depression was not selectively more pronounced among older people with physical impairments. However, the association appeared to be most specific for Ss with a small social network and those with a low sense of mastery.
http://dx.doi.org/10.1023/A:1006580708223
http://hdl.handle.net/1871/39709
Examined the type and stability of social support networks providing instrumental and/or emotional support to a sample of 2,709 older Dutch adults aged 55-89 yrs. Results show that the hierarchy of instrumental support differs by partner status of the older adult, but the hierarchy in emotional support does not vary with the availability of partner or children. Multi-level regression analyses using data at an 11 month follow-up indicate that 46 bereaved older adults received increased instrumental support from their network, while their receipt of emotional support remained unchanged. Shifts in the hierarchy of instrumental support were observed, but not in the hierarchy of emotional support. Older people who suffered a decrease in physical mobility received more instrumental and emotional support, but the ranking of supporter types changed little. It is concluded that despite changes in intensity of support, the hierarchies of types of supporters have generally remained stable over time.

http://hdl.handle.net/1871/18943

The financial position of older adults in the Netherlands is a heterogeneous one. Gender, living arrangement and age are among the most important determinants of household income levels, as has been illustrated with macro level data. However, the interconnectedness of current characteristics of older males and females with life-course experiences in the field of labor market participation and partner relationships, is hypothesized to be of crucial importance to explain the differences in financial opportunities and resources older adults are confronted with. To investigate the financial position of older men and women, data from the NESTOR 'Living Arrangement and Social Networks' program, based on 4494 face-to-face interviews, have been used.

http://hdl.handle.net/1871/49168
Examined the direct and buffer effects of various aspects of social support and personal coping resources on depressive symptoms in a community-based sample of 1,690 55-85 yr olds, of whom 719 had no chronic disease, 612 had mild arthritis and 359 had severe arthritis. Results showed that persons with arthritis had more depressive symptoms than persons with no chronic diseases. Irrespective of arthritis, the presence of partner, having many close social relationships, feelings of mastery and a high self-esteem were found to have direct, favorable effects on psychological functioning. Mastery, having many diffuse social relationships, and receiving emotional support seem to mitigate the influence of arthritis on depressive symptoms, which is in conformity with the
buffer hypothesis. Favorable effects of these variables on depressive symptomatology were only, or more strongly, found in persons with severe arthritis.

This study focuses on the role of social support and personal coping resources in relation to mortality among older persons in the Netherlands. Data are from a sample of 2,829 noninstitutionalized people aged between 55 and 85 years who took part in the Longitudinal Aging Study Amsterdam in 1992-1995. Social support was operationally defined by structural, functional, and perceived aspects, and personal coping resources included measures of mastery, self-efficacy, and self-esteem. Mortality data were obtained during a follow-up of 29 months, on average. Cox proportional hazards regression models revealed that having fewer feelings of loneliness and greater feelings of mastery are directly associated with a reduced mortality risk when age, sex, chronic diseases, use of alcohol, smoking, self-rated health, and functional limitations are controlled for. In addition, persons who received a moderate level of emotional support (odds ratio (OR) = 0.49, 95% confidence interval (CI) 0.33-0.72) and those who received a high level of support (OR = 0.68, 95% CI 0.47-0.98) had reduced mortality risks when compared with persons who received a low level of emotional support. Receipt of a high level of instrumental support was related to a higher risk of death (OR = 1.74, 95% CI 1.12-2.69). Interaction between disease status and social support or personal coping resources on mortality could not be demonstrated.

1996

The personal networks of elderly people reflect their social opportunities and personal choices to maintain a specific set of relationships with relatives, neighbors, friends, acquaintances, and so on. Network analysis is the method used to identify and examine the structural and functional features of the network of the older adult. The conceptualization and operationalization of the personal network depend on the subject of research. Five approaches to define personal network membership are presented and discussed. The five approaches differ regarding the part of the personal network that is mapped, and result in networks of different sizes and compositions. Regardless of the type of network delineation, a distinction can be drawn between the star network (data available on relationships with the focal person) and the full network (data available on all the network relationships). Features of the structure and content of both types of networks are presented. Finally, network analysis methods are presented and discussed, including ways to analyze hierarchical databases.

This article aims at testing an assessment schedule which is generally applied in order to determine the necessity and urgency of admission into a home for the aged. The central question concerns the extent to which this schedule contributes to (1) objectivity, implying that applicants with similar 'needs' will have an equal opportunity of being admitted to the requested provision, and (2) efficiency, meaning that a clear distinction in the urgency of admission is being made according to the seriousness of 'needs'. The research therefore concentrates on two topics. First, the homogeneity and statistical reliability of the assessment schedule, i.e. the questionnaire which is used for measuring the need for (institutional) care. Second, the statistical association between the measured need and the urgency of admission into a home for the aged. The research rests upon data on 164 older adults who have requested for admission; this data were obtained by a local agency responsible for need-assessment in relation to institutional care. The findings are as follows: (1) the homogeneity of the instrument can be improved, (2) the reliability is fairly good, (3) the association between 'need' and 'urgency of admission' is not very strong, notwithstanding the fact that (4) persons with lower scores on ADL- and IADL-capacities, with more psycho-social problems and with stronger feelings of anxiety have significantly better opportunities of being admitted to a residential facility. It is concluded that the association between 'need' and 'urgency of admission' might be improved by refining the assessment schedule and standardizing its application.

Objective: Develop and test a self-administered questionnaire that measures perceived and actual functional limitations in rising and sitting down. Setting: Private practices for physical therapy and outpatient clinics of hospitals and rehabilitation centers. Patients: 345 outpatients (43% male, aged 14 to 92 years) with different grades of functional limitations and different types of lower extremity orthopedic or rheumatologic disorders. Methods: The Questionnaire Rising and Sitting Down (QR&S) was developed on the basis of a literature review and careful operationalization of functional limitations. Five dimensions concerning different objects (high chair, low chair, toilet, bed, and car) and one global dimension were postulated to be contained in the instrument. Mokken scale analysis was used to test the postulated dimensions (scalability coefficient H). Furthermore, robustness with respect to patient characteristics was determined, as well as intratest reliability (reliability coefficient Rho), test-retest reliability (intraclass correlation coefficient [ICC]), content validity (coverage of operationalized aspects), and construct validity (testing of seven hypotheses). Results: Mokken scale analysis confirmed the existence of 5 object dimensions (N = .53-.59). However, two global dimensions were found (H = .50-.54). The resulting hierarchical scales, consisting of subsets of the 32 final QR&S items, are robust and measure functional limitations in a reliable (Rho .77-.91; ICC .72-.90) and valid (3 out of 4 aspects covered, 2 hypotheses rejected for 3 out of 7 scales) manner. Conclusion The QR&S is a reliable and valid self-administered questionnaire. It consists of hierarchical scales and measures perceived and actual functional limitations in rising and sitting down.

Presents results from the Longitudinal Aging Study Amsterdam regarding the prevalence of both major (MaD) and minor depression (MiD) and age-related shifts in the patterns of associations with both vulnerability and stress. A random sample of 3,056 adults (aged 55-85 yrs) was obtained from 3 regions in the Netherlands. The prevalence of MaD was 2.02% and that of MiD, 12.9%. 14.9% had clinically relevant levels of depressive symptoms. Except in the youngest age group, women had higher prevalence rates for both MaD and MiD. Rising rates of depression with age were only found for women. Bivariate associations of both MaD and MiD with a broad range of risk factors did not differ dramatically between the sexes or age groups. Results suggest that MaD in the elderly is more often the exacerbation of a chronic mood disturbance, with roots in long-standing vulnerability, while MiD is more often a reaction to the stress encountered in later life.

Het geven van steun aan anderen kan in het perspectief van ruil gezien worden. Mensen die steun geven, verwachten (later) ook weer steun terug te ontvangen. De relaties waarbinnen steun gegeven worden, komen dan, als de steun wordt terug gegeven, in balans. Deze balans noemen we ook wel wederkerigheid. In het algemeen trachten mensen hun onderlinge relaties in balans te houden. Als men echter verwacht dat men later steun nodig heeft, zou de relatie nu juist uit balans gebracht kunnen worden door meer steun te geven dan men zelf ontvangt. Dit noemen we investeren. Men hoopt dat die investering zich later, wanneer men zelf steun nodig heeft, uitbetaalt. Voor ouderen is het belangrijk te investeren omdat er kans is dat zij later, bijvoorbeeld als gevolg van een verslechterende gezondheid, steun nodig hebben. Investeringen in sommige relaties, bijvoorbeeld in de relaties met de kinderen of met goede vrienden, kunnen beter zijn dan in andere relaties, bijvoorbeeld relaties met kennislen. Zo is het minder zeker dat de aan kennislen gegeven steun later teruggegeven wordt dan dat men steun van kinderen of vrienden terugkrijgt. Het investeren in relaties waarbij een grote kans bestaat dat men ook steun terugkrijgt, noemen we strategisch investeren. Deze theorie wordt bevestigd in een onderzoek onder 413 ouderen, waarin gemiddeld vijf van hun persoonlijke relaties betrokken zijn. Dit zijn relaties met de partner, met kinderen en met andere familieleden, maar ook relaties met buren, vrienden, kennislen en mensen die men van een vereniging kent.

Methods for delineating personal networks in surveys contain complex instructions for the interviewers. We investigate the magnitude of interviewer effects on the network size in a large longitudinal survey among the elderly, and try to explain differences between interviewers by their prior experience with surveys and their level of education. The results show that interviewers with minor experience and with low education generate relatively large networks. A revised version is published as: Van Tilburg, T.G. (1998). Interviewer effects in the measurement of personal network size: A non-experimental study. Sociological Methods & Research, 26, 300-328.

Met de toenemende vergrijzing is er ook een toenemende aandacht voor ouderen. Representatieve beschrijvende en verklarende gegevens over de samenstelling, kwaliteit en andere kenmerken van de sociale netwerken van ouderen in Nederland waren tot voor kort slechts in beperkte mate voorhanden. Antwoorden op vragen als 'Hoe groot zijn de netwerken van ouderen?', 'Wat is de omvang en de aard van de informele ondersteuning die ouderen krijgen?', en 'Welke factoren veroorzaken verschillen in de omvang van netwerken en de daarbinnen verkregen steun?' zijn van belang voor de overheid bij het voorbereiden van beleid op ondermeer de terreinen van huisvesting en zorg. In het onderzoeksprogramma 'Leefvormen en sociale netwerken van ouderen' worden deze vragen beantwoord. In dit artikel gaan we specifiek in op de geografische spreiding van netwerken.

1994

Older adults' personal network size and the intensity of the instrumental and emotional support received and given within their personal relationships are described, based on data from 2,891 respondents (aged 55-85) of the LASA study. Differences in network size were observed according to differences in sex, age, the availability of a partner, the strength of church affiliation, education, income and financial status. For instrumental support received and emotional support given and received most of the variance is explained by network size only. For instrumental support given,
the addition of the variables sex, availability of a partner and age contributed clearly to the explained variance: males, respondents with a partner and younger respondents gave more.

1993

1992

Bepalingen van subjectieve en intersubjectieve wederkerigheid komen in grote mate overeen: beide laten zien dat de netwerken van ouderen gemiddeld ongeveer wederkerig zijn. Het verschil in gemiddelde is te verwaarlozen en de onderlinge samenhangen zijn redelijk sterk. Er zijn echter ook verschillen: de gegevens over de uitwisselingen verkregen van de ouderen komen niet geheel overeen met die van de netwerkleden. Vanwege het ontbreken van een criterium variabele kunnen geen conclusies getrokken worden over wat de beste bepaling van wederkerigheid is. Er zijn echter wel aanwijzingen voor een systematisch methode-effect. Het kan zijn dat de ouderen de gegeven emotionele steun relatief overschatten en de instrumentele steun onderschatten, dat wil zeggen een tekort in instrumentele wederkerigheid (te weinig steun geven) compenseren met een overschot aan emotionele wederkerigheid (meer steun geven).

Sequence effects are discussed as a methodological problem in the measurement of reciprocity of social support. It is hypothesized that the likelihood that a relationship is reciprocal will be greater if the pairs of questions on receiving & giving support immediately succeed each other in the interview than if an entire set of questions on receiving support precedes the entire set of reversed questions. Analysis of responses to a survey conducted with an experimental design among 179 elderly in the Netherlands does not refute this hypothesis; a method effect of approximately 10% was observed in the expected direction. The method effect was also evident in results regarding the exchange orientation: under the pairwise condition, no significant associations were observed between exchange orientation & reciprocity, whereas significant associations in the expected direction were observed under the blockwise condition.

Changes in one's personal network can be expected to follow after retirement. A certain loss of relationships, for example with colleagues, is inevitable. How do people who are either about to retire or have recently done so react to this life event? Do they form new relationships or deepen their existing ones? Which type of relationships are most likely to be terminated? Is over benefiting or under benefiting in support a significant aspect in the termination of relationships? This article addresses these questions on how retirement affects support networks. The data were obtained from 50 men, interviewed before and after retirement. At T2 approximately a third of the personal relationships were no longer part of the network. The average size of the networks had not changed. A larger proportion of network members was unemployed and most of the relationships with colleagues were terminated. The relationships were evaluated as being more pleasant and the frequency of the contact was higher. On average, the relationships at T2 were with older persons and tended to be more frequently with an acquaintance than those at T1. More exchanges were carried out at T2 than at T1. They were mainly exchanges in which support was given by the respondents to network members, so that there was a small reduction in the overall reciprocity. The results confirm the hypothesis concerning the significance of reciprocity for the stability of exchange relationships.

1991

and 52 males nearing retirement. The 4 indices showed that the respondents' relationship networks were strongly reciprocal. The results did not make it unequivocally clear whether overbenefiting (vs underbenefiting) and loneliness were linked via a U-shaped association or via a linear or inverse U-shaped association.

The robustness of J. de Jong-Gierveld's loneliness scale was examined through analysis of data from six Dutch surveys using different modes of data collection (three using self-administered paper questionnaires, two using face-to-face interviews, and one using telephone interviews). Among the findings are: collection mode did not affect robustness; questionnaires did not lead to higher item nonresponse; questionnaires and telephone interviews resulted in better interitem homogeneity and person scalability than face-to-face interviews; and absence of an interviewer did not result in greater self-disclosure and higher scale means. The robustness of the scale is discussed as questionable, however, in regard to interitem homogeneity and person scalability.

It has been suggested that differences in loneliness among those living with a partner are associated with gender and stages of the life cycle. The present study examines whether or not such an association exists, and if this is found to be the case, whether it can be interpreted in terms of differences in the supportive network and differences in the importance attached to relationships. Data from 165 respondents show that men are, on average, more lonely than women, and that parents with older children living at home are, on average, most lonely. The networks of the males are generally less supportive than those of females, and men tend to attach greater importance to the partner relationship than do women. The findings that parents with older children are generally most lonely cannot be explained in terms of the importance attached to relationships, and only partially in terms of networks characteristics. These respondents receive relatively much support from the children who are members of their household, and relatively little from relationships outside their household. It is put forward that family nuclearization may be an underlying process.

(from the chapter) deals with the implications of distinguishing between the mechanisms (operating within social relationships) of dominance (a single dominant confidant), compensations (others who compensate for needs not met by the confidant), and additivity (different persons providing different elements that add to the total necessary support) for designing survey research on the impact of the supportive network of relationships on individual well-being /// we prefer a procedure that first identifies the appropriate relationships in the network and then assesses whether or not the relationships are characterized by each of a number of aspects of support / the quantity of information respondents must provide increases in proportion to the number of relationships under consideration and to the number of aspects of support that are distinguished / the central question addressed is whether such an intensive examination of the supportive network of relationships

*Publications by Theo van Tilburg, p. 64*
produces enough additional information to justify the extra effort required of both the respondent and the researcher /// the data are from a survey that focused on the association between the supportive network and loneliness / a first research question to be dealt with is: do people in fact often have several supportive relationships at their disposal / a second research problem: does an intensive examination of the network of relationships, with the help of a procedure based on the idea of additivity in relationships, produce a stronger association with loneliness than an examination that starts from the relationship with the confidant (assuming dominance, respectively compensation).

http://hdl.handle.net/1871/49566
(from the chapter) compare the type and content (i.e., actual emotional and instrumental exchanges) of primary relationships as indicators of support in relationships / if the relationship type is a valid indicator of support, then differences in support should vary systematically with differences in relationship type / if the relationship type and the relationship content are valid indicators, both measures should be strongly associated with a straightforward measure of the intensity of support / examine these assumptions using results from an empirical survey /// the leading question will be: which operationalization of support is adequate -- the one based on the type of a relationship, or the one starting from the content of a relationship / the hypothesis to be rejected is: the assessment of relationship type is sufficient for the assessment of the intensity of the support in the relationship.

Interview data collected in 1985/86 from divorced men and women (N = 127) in Purmerend and Haarlemmermeer, the Netherlands, are used to investigate the effects of the loss of the partner relationship and the loss of support from other relationships on loneliness. It is found that such loss increases loneliness, but that if nonkin relationships are among the strongest remaining supportive relationships, the chance of experiencing loneliness decreases. These results indicate that if marriage is disrupted when an individual has few supportive relationships outside the nuclear family, the chance of severe loneliness is high. It is therefore desirable from the point of view of prevention to stimulate the development & maintenance of a varied relationship network.

A Rasch-type loneliness scale was administered in two studies. The first involved 708 unemployed, occupationally disabled, and employed men and women. The second involved 412 married, unmarried, divorced, and widowed women and men. The effects of being with or without a partner, the S's evaluation of the supportive function of the partner, and different types of problem situations were examined. Results reveal a decrease in loneliness scores as a function of the positive evaluation of partner support. A buffer effect for partner support was not found. However,
the effect of the partner's support varied with the type of problems. It is concluded that in the event of externally caused problems, the support provided by the partner is of some use but falls short in dealing with the problem. The support from other individuals in the network seems indispensable.

1987

Summation of support received from individual relationships produces a figure reflecting the total support received from the respondent's personal network. Support received from respondent's personal network can also be assessed globally by asking questions about the respondent's network as one whole. A survey with 419 adults used both measurements. A comparison of the two instruments demonstrated that global assessment corresponds to a greater degree with a summation derived from eight relationships than with one derived from seven or fewer relationships. However, the correlation was too small (r = .461) to allow the conclusion that both instruments measure the same. The results of global assessment deviated in the case of some respondents from what might be expected on the basis of data derived from all the respondents. These deviations were bound up with evaluative factors. This indicates that global assessment of support can lead to confounding of social support with loneliness.

Summary

Loneliness has a negative impact on personal health and social participation and is regarded both as a problem for individuals and an issue for society. There is also a taboo surrounding loneliness and it is difficult to identify. Loneliness seems to emerge through a gradual and almost imperceptible process of accumulating risk factors, such as a shrinking social network, poor health and a perception of less control over one’s life. The way to safeguard against loneliness is to tackle these risk factors.

The aim of this study is to provide an insight into the factors that play a role in the occurrence of loneliness in the course of people’s lives, particularly during the second half of life, and to show how loneliness is related to quality of life.

After presenting an overview of what we already know from previous research, we present a number of studies conducted among various populations regarding which risk factors are related to loneliness in an ageing population. We examine both cohorts and the individual lives of older persons. In addition, we focus on two vulnerable groups who receive long-term care and support: nursing home residents and people who receive support as part of the Social Support Act (Wet maatschappelijke ondersteuning – Wmo). Finally, we examine the association between loneliness and quality of life among these vulnerable members of society.

There are various approaches to investigating loneliness. In this report, we adopt the cognitive discrepancy approach as a starting point. This states that loneliness is the result of an evaluation of the perceived discrepancy between the social relationships that an individual would like and their real-life social relationships. We define loneliness as a perceived lack of social relationships, or a perceived lack of quality in those relations. Perceptions of loneliness can range from moderate or unpleasant to strong or unbearable. Loneliness was measured using the original or abbreviated loneliness intensity scale (eleven and six questions, respectively) (De Jong Gierveld and Kamphuis 1985, De Jong Gierveld and Van Tilburg 1999). On the basis of the respondents’ scores on this scale, they were divided into three categories: no loneliness, moderate loneliness or severe loneliness.

Results

The likelihood of loneliness among older persons is decreasing; however the number of lonely older persons is rising

It is often assumed that loneliness among older persons in the Netherlands is increasing. Chapter 3 examines the following questions: Has the prevalence of loneliness among older persons changed in the last twenty years? And which factors have been responsible for this trend?

In the period from 1996 to 2016, average levels of loneliness among people aged 55 and older fell by 0.2 to 0.8 points on a scale of 0 to 11. The average individual older person is therefore less lonely than its contemporary twenty years ago. A lot has changed over those twenty years. An 80 year old of today is different from an 80 year old then. Improvements in social contact have contributed to a decline in loneliness. On average, more older people have a partner and their social network is wider and more diverse. Older people also feel in control of their own lives. In short, because the situation of older people improved, the average likelihood of feelings of loneliness has fallen. At the same time, the number of older persons has increased. For this reason, there were more lonely older persons in real terms in 2016 than there were in 1996.

Loneliness among older persons increases with age due to the loss of a partner and social relationships

Chapter 4 explores how feelings of loneliness develop in the lives of older persons. Many over-55s become more lonely as they get older. Between the ages of 55 and 95 years, the proportion of
those experiencing moderate loneliness increases from 18% to 53%, and the proportion of very lonely people increases from 2% to 9%. This increase can be explained by the changes that often occur during this phase of life. The loss of social relationships raises the average level of loneliness on a scale of 0 to 11. The loss of a partner (+1.1 point), a smaller and less varied social network (+0.1 point) and the loss of daily social contact (+0.3 point) are the most common factors. There is also the perceived loss of control over life (+0.4 points), and older people are more likely to have to rely on professional care and support (+0.3 points). Health issues (+0.1 point) and loss of income (+0.1 point) play a limited role in the rise in loneliness as people become older. There is one important exception to this increase. This concerns older persons with serious health problems. Following relocation to a nursing home or residential care centre, people experience less loneliness (-0.6 points) than when they lived independently.

People aged over 85 who live in a nursing home are less lonely
Nursing homes do not have a good image. They are often seen as lonely places. Chapter 5 investigates which nursing home residents experience loneliness. Approximately five out of ten respondents in nursing homes experience loneliness: one in ten feel very lonely and four in ten feel moderately lonely. Loneliness among the over-85s in nursing homes is lower than loneliness among younger residents. But loneliness among nursing home residents aged 85 and above is lower than loneliness among people of the same age who are living independently. This corresponds with the findings presented in chapter 4. Loneliness among older persons living independently increases as they become older. Among older persons who are admitted to a nursing home due to poor health, loneliness decreases. Nursing home residents who experience less loneliness are older, have a partner, perceive more control over their own life and have more social contacts. They are more likely to feel lonely if they have poor mental health and if they are highly educated. People are less lonely when they receive more visits and when children and other family members call them often (or if they keep in touch using a video chat program). Residents who go to visit someone outside the nursing home are also less lonely.

Those receiving support under the Wmo feel more lonely because they live alone and have health problems
More and more people who need support are living independently up to a higher age. Chapter 6 investigates which people receiving support under the Wmo experience loneliness, and which factors play a role.
More than half of those living alone and receiving Wmo support (aged over 18 years) report feelings of loneliness. Almost one in five experience severe feelings of loneliness. That share is higher than in the adult population as a whole. Those receiving support under the Wmo are more often lonely if they live alone, have motor and/or visual impairments, have experienced variable or deteriorated health in the past year, and/or experience fatigue and/or psychological and/or psychosocial problems. Those between the ages of 55 and 74 are also feeling more lonely than those aged between 35 and 54 years. They are less often lonely when there are enough opportunities to maintain social contacts independently or with help, when they have weekly contact with family members, friends, neighbours and/or club members, and when they are more resilient, self-reliant and able to participate socially. The involvement of a caregiver and receiving customised services under the Wmo also reduce the chance of loneliness.

Lonely, but happy
Are lonely people necessarily always unhappy? In chapter 7 we investigate the extent to which loneliness is associated with happiness among those with long-term support needs. We define loneliness as the degree to which a person perceives a lack of (meaningful) social relationships, and happiness as their degree of satisfaction with life in general. We found that both among those living independently and receiving support under the Wmo, and those living in nursing homes, there was no linear association between feelings of loneliness and lower levels of overall happiness. We found both people who were ‘lonely and unhappy’ and people who were ‘lonely but happy’. The lonely and unhappy group was characterised by poorer health, both among the Wmo group and among nursing home residents. Only a small group of 2%
to 4% felt very lonely and very unhappy. A group of around 10-15% felt very lonely and yet reasonably happy. It is also interesting to note that approximately half of nursing home residents and the Wmo group felt happy and not lonely.

**Insights from this study**
Which insights do the results of this study provide, and which gaps in our knowledge can be identified? In Chapter 8, we consider these concluding questions.

**Combating loneliness among the elderly**
Reducing loneliness is challenging because the number of older persons is rising steadily. Although the individual likelihood of loneliness has fallen over the past twenty years, this fall is too small to stop the number of lonely people from rising in absolute terms. This study identifies specific trends that could help reduce the chance of loneliness at the individual level. For example, as we have explained, the social networks of older persons have become wider and more diverse over the past twenty years. Another important trend is the increase in both the number of older persons living independently and their sense of control over their own life. This has reduced the likelihood that an individual will experience loneliness. In addition, there will always be life events that cannot be prevented, such as the loss of a partner or a serious illness. These dramatic life events increase the risk of loneliness. Although these life events are difficult to predict and it is not always clear whether, and how, they will result in loneliness, they are an integral part of old age, a life phase in which people are already more likely to experience loneliness.

**Living independently or in a nursing home**
This study finds that living in a care home or nursing home can help to protect people with serious health problems from feelings of loneliness. After being admitted to a care home or nursing home, the risk of loneliness decreases. This has implications for the government's policy ambition of enabling older persons to live independently for longer. On the one hand, this reflects what many older persons themselves prefer, but on the other hand tighter requirements have made it more difficult for older persons to move to sheltered accommodation in the form of a care home or nursing home. However, moving to a care institution provides the oldest and most vulnerable people with some degree of protection against loneliness.

**Improving quality of life**
The assumption that combating loneliness is a way to make people happier does not seem to hold true entirely, according to this study. The situation is more nuanced than this. Tackling loneliness often involves focusing on increased social contact. However, the perceived quality of life (or happiness) of frail people invariably involves more than just a lack of social contact, and also relates to health, finding a purpose in life, activities and other issues. Promoting better mental health, for example, contributes directly to people's perceived levels of happiness. Social-cultural activities that involve both socialising and cognitive activities can help give meaning to people's lives. Participating in artistic or sporting activities, for instance, can both contribute to overall happiness and help to prevent loneliness in different ways.

**Knowledge gaps**
This study explores various aspects of loneliness. The dynamics between these factors have not yet been studied. In order to develop a more coherent approach to tackling loneliness, greater insight is needed into these dynamics and interaction between the factors involved in loneliness. Loneliness does not have one single cause. It has multiple causes, and these can reinforce or counteract one another. This study shows that people who are at increased risk (and where there are no countering factors) are more susceptible to loneliness. The interplay of the factors involved in loneliness is complex and we have yet to understand this fully. Theories and models may help us to do this. Many different factors can play a role in the development of feelings of loneliness, as this study shows. According to the theory used in this study, for example, loneliness arises when there is a mismatch between the life that a person would like to live and the reality of
their life with respect to social relationships; this mismatch can become more severe and longer-lasting over time. It is therefore important to check what people actually want first, before deciding on a solution or approach. Loneliness is a persistent problem and combating it has no simple solutions.

Samenvatting

Ouderen steeds minder eenzaam

Kwetsbare ouderen beter af in verpleeghuis

- Individuele kans op eenzaamheid van ouderen neemt af maar aantal eenzame ouderen stijgt
- Eenzaamheid van ouderen neemt toe met leeftijd door verlies van partner, sociale relaties en regie over het leven
- Kwetsbare ouderen zijn in verpleeghuizen minder eenzaam
- Zelfstandige wonende Wmo-melders zijn vaker eenzaam wanneer ze alleen wonen, moeite hebben met onderhouden van contacten en fysieke- en psychosociale problemen ervaren
- Slechts klein deel van de kwetsbare eenzamen ook ongelukkig.
- Eenzaamheid kent niet één oorzaak

Dit onderzoek combineert drie deelstudies van een panel van 5.000 ouderen, 2.300 zelfstandig wonende Wmo-melders en 950 verpleeghuisbewoners.

Eenzaamheid van ouderen neemt af

In de periode van 1996 tot 2016 daalde de gemiddelde eenzaamheid van mensen van 55 jaar en ouder met 0,2 tot 0,8 punten op een schaal van 0 tot 11. Dat komt onder meer omdat ouderen vaker een partner hebben, een groter en diverser netwerk en een groter gevoel van regie over het leven in vergelijking met twintig jaar geleden. Tegelijkertijd groeit de oudere bevolking en daarom zijn er in 2016 meer ouderen eenzaam dan in 1996.

Eenzaamheid van ouderen neemt toe met leeftijd

Dat veel ouderen eenzamer worden is te verklaren door verliezen in deze levensfase. Verlies van sociale relaties verhoogt de kans op eenzaamheid. Partnerverlies, een kleiner en minder gevarieerd netwerk, en verlies van het dagelijks netwerkcontact zijn veelvoorkomende veranderingen. Ook is er verlies van ervaren regie over het leven en is men vaker afhankelijk van professionele zorg en ondersteuning. Gezondheidsverlies en verlies van inkomens spelen een beperkte rol bij de toename van eenzaamheid.

Kwetsbare 85-plussers in verpleeghuizen minder eenzaam

85-plussers met ernstige gezondheidsproblemen zijn na verhuizing naar een verpleeghuis minder eenzaam dan toen zij nog zelfstandig woonden. Ongeveer vijf van de tien ondervraagde bewoners in verpleeghuizen voelt zich eenzaam, waarvan één bewoner sterk eenzaam en vier bewoners matig eenzaam. De eenzaamheid onder de 85-plussers in verpleeghuizen is lager (10% versus 22% sterk eenzaam) dan onder de jongere bewoners (55 – 74 jaar) van een verpleeghuis. De eenzaamheid onder de verpleeghuisbewoners van 85 jaar en ouder is ook lager (10% versus 14% sterk eenzaam) dan onder hun leeftijdsgenoten die zelfstandig wonen.

Zelfstandige wonende Wmo-melders zijn eenzamer

Ruim de helft van de Wmo-melders van 18 jaar en ouder voelt zich eenzaam. Bijna een op de vijf voelt zich sterk eenzaam. Dat aantal is hoger dan in de algemene bevolking van 18 jaar en ouder. Wmo-melders zijn vaker eenzaam wanneer ze alleen wonen, verslechterde of wisselende fysieke en psychosociale gezondheidsproblemen hebben. Wmo-melders zijn minder eenzaam naarmate
ze mogelijkheden hebben om contacten te onderhouden, meer contact met familie, vrienden, buren en/of clubleden hebben, veerkrachtiger en zelfredzamer zijn en meer meedoen aan sociale activiteiten. Ook de aanwezigheid van een mantelzorger en ontvangen van een maatwerkvoorziening vanuit de Wmo verlaagt de kans op eenzaamheid.

Deel kwetsbare eenzamen toch gelukkig
Zowel bij zelfstandig wonende Wmo-melders als bij bewoners van verzorgings- en verpleeghuizen betekent eenzaamheid niet vanzelfsprekend dat men zich ook ongelukkig voelt. Slechts 2% tot 4% van deze groep voelt zich sterk eenzaam en zeer ongelukkig. De eenzaam ongelukkigen onderscheiden zich door een slechtere gezondheid, zowel onder Wmo-melders als onder verpleeghuisbewoners. Ongeveer de helft van de verpleeghuisbewoners en van de Wmo-melders voelt zich overigens niet eenzaam en wel gelukkig.

Eenzaamheid kent niet één oorzaak
Eenzaamheid heeft meerdere oorzaken, die elkaar kunnen versterken of afzwakken. Deze studie toont dat mensen bij wie de risicofactoren, zoals partnerverlies en minder ervaren regie toenemen (en de bescherming afneemt), vatbaarder zijn voor eenzaamheid. Eenzaamheid is een ervaren verschil tussen wens en werkelijkheid ten aanzien van sociale relaties, die geleidelijk sterker en langduriger kan worden. Het is dus van belang om eerst na te gaan wat de wensen zijn van mensen, voordat men een oplossing of aanpak bedenkt.
